The CERENAT study by **Coureau et al. (2014)** [90] is a multicenter case-control study conducted in four areas of France. Cases were defined as all subjects aged 16 and over diagnosed between June 2004 and May 2006 and living in one of four French areas (Gironde, Calvados, Manche, Herault) with a benign or malignant brain tumor (with specific ICDO-3 codes). These tumors were verified either through neuropathological, clinical or radiological assessment. For each case, two controls with no history of CNS tumors were randomly selected from electoral rolls and matched on age (±2 years), sex and department of residence. Exposures were determined through non-blinded, face-to-face application of questionnaires; proxies were given a simplified questionnaire. Regular users were defined as people who were phoning at least once per week for 6 months or more and at least one-year prior to diagnosis. An adjustment was made for subjects using hands-free calling or sharing their phones with others. The analyses for gliomas included 253 cases and 504 controls with a participation rate of 66% for gliomas and 45% for controls. The OR for regular users versus others was 1.24 (0.86-1.77) adjusted for level of education and exposure to ionizing radiation. Exposure-response analyses were conducted for time since first use (p=0.17, ≥10 years 1.61, 0.85-3.09), average calling time per month (p<0.001, ≥15 hours 4.21, 2.00-8.87), average number of calls per day (p=0.04, 5-9 calls 2.74, 1.33-5.65, ≥10 calls 1.78, 0.88-3.59), cumulative duration of calls (p=0.02, ≥896 hours 2.89, 1.41-5.93) and cumulative number of calls (p=0.41, ≥18,360 calls 2.10 (1.03-4.31). Analyses excluding proxies saw almost the same results. Among the heaviest users (≥896 hours cumulative duration of calls), the OR for 5-year latency was 5.30 (2.12-13.23), for occupational users the OR was 3.27 (1.45-7.35) and for exclusive use in an urban setting the OR was 8.20 (1.37-49.07). Ipsilateral use (0.70, 0.46-1.07) was higher than contralateral use (0.30, 0.17-0.52), however, these findings were questioned by **Hardell and Carlberg (2015)** [91] because the approach used was different than that used in their analyses and in the Interphone Study. The authors responded [92] and, using the same method as **Hardell and Carlberg (2015)** [88], obtained an OR for ipsilateral use of 4.21 (0.70-25.52) and for contralateral use of 1.61 (0.36-7.14). They also applied the same method used in **Inskip et al. (2001)** [44] and obtained an OR of 2.40 (1.002-5.73). The major weaknesses of this study are the response rates and the use of questionnaire data for exposure. The authors addressed concern for recall bias by carefully assessing exposure in the highest exposed individuals. They found that there may be some small concern for exposure misclassification, but it is likely to be non-differential and is unlikely to have affected the final results. (Table 1, Table 2, Table 3, Table 4, Table 5, Table 6, Table 7)

Yoon et al. (2015) [93] conducted a case-control study in five areas of Korea (Seoul, Gyeonggi-do, Gyeongsang-do, Jeolla-do, Chungcheong-do, Gangwon-do, and Jeju-do). Cases (285 participated, 142 refused, 465 had excessive pain and 5 had no matched control) were identified as glioma patients between the ages of 15 and 69 years of age and controls (285 participated, 354 refused, 7 had excess pain and 405 had no matched case). Cases and controls came from the recruiting hospitals and were given a questionnaire during the initial interview. Cases were also excluded if they died during the course of the study. There were some significant differences between cases and controls (residential region, education, patient or proxy, use of dye, alcohol use, computer use and use of electric blankets). Users were defined as having more than 1 year of cellular phone use. The OR for users was 1.17 (0.63-2.14) for all respondents and 0.94 (1.46-1.89) for self-respondents. The largest group of users had used both analog and digital phones and they had an OR of 1.89 (0.96-3.81). Lifetime years of use, cumulative hours of use, average number of calls received daily, average number of calls sent daily and average duration of calls had ORs that were generally greater than 1.0, included 1.0 in the 95% confidence interval, and did not appear to show dose-response although no test was done. Using the method of **Inskip et al. (2001)** [44] gave a relative risk (RR) of 1.26 (p=0.05) for all respondents and 1.43 (p=0.01) for self-respondents. ORs for ipsilateral versus contralateral use were very mixed and seldom included the OR from the original evaluation as falling between the ORs for the two sides (it appears they used the same method as the **CERENAT study (2014)** [90] but this cannot be verified). Besides the usual possibility of recall bias in these types of studies, this study's weaknesses include poor reporting of the methods, an unusual exclusion of patients due to pain and very high refusal rates for both cases and controls. (Table 1, Table 2, Table 3, Table 6)

4.1.1.2 Cohort Studies

Schuz et al. (2006) [94] extended the evaluation of a retrospective cohort study in Denmark [95]. They identified 723,421 cellular telephone subscribers in Denmark from 1982 to 1995, 420,095 of whom could be identified as individuals and became part of the cohort. The other 303,326 were excluded because the user was listed as a corporation (200,507) or excluded for other reasons (102,819). Approximately 85% of the cohort members were males. Only first cancer diagnoses were used in this analysis and the ending date of follow-up is December 31, 2002. The observed cancers in the cohort were compared to the expected numbers in the Danish population using the Danish Cancer Registry after subtracting the number of cancer case patients and person-years observed in the cohort from those in the registry.

There was a significant decrease in all cancers for males (RR 0.93, 0.92-0.95) and a marginally significant increase in females (1.03, 0.99-1.07). All of the RRs for cancers in males, including brain and CNS tumors (0.96, 0.87-1.05), lacked statistical significance with 14 of the 20 grouped organ sites having RRs below 1. In females, all smoking-related sites, cervix/uteri and kidney tumors showed significantly increased RRs with brain and CNS tumors non-significant (1.03, 0.82-1.26). For males and females combined, gliomas (1.01, 0.89-1.14), meningiomas (0.86, 0.67-1.09) and cranial nerve sheath tumors (0.73, 0.50-1.03) were all non-significant. There was no increase with years on use in both males and females for brain and CNS tumors (p=0.51) or leukemias (p=0.69).

Frei et al. (2011) [96] conducted an update of the Danish cohort study using the same information on cellular phone subscriptions (1982-1995); hence the update is only with regard to tumor rates and contains no information on cellular phone subscriptions post 1995. Only first cancer diagnoses were used in this analysis and the ending date of follow-up is December 31, 2007. To obtain information on socioeconomic factors, they used the CANULI cohort study data [97] which includes all Danes aged 30 or older born after 1925 in Denmark. Because of eligibility requirements for CANULI, the number of subscribers was reduced by 54,350; thus, the follow-up contained 358,403 subscription holders.

There was a significant decrease in all cancers for males with subscriptions (RR 0.96, 0.95-0.98) and a marginally significant increase in females (1.02, 0.98-1.06). There were slight increases in central nervous system tumors for both males (1.02; 0.94-1.10) and females (1.02; 0.86-1.22) with no apparent increase in risk as years of subscription increased. There was a stronger increase for gliomas alone in males (1.08; 0.96-1.22) but not in females (0.88; 0.69-1.40) with the highest RRs in males for only 1-4 years of subscription (1.20; 0.96-1.50) and the lowest for ≥13 years of subscription (0.98; 0.70-1.36); there was no exposure response in females. There is a chance some of the gliomas could have fallen in the "other and unspecified" category and those saw RRs above 1 for both males (1.12; 0.95-1.33) and females (1.19; 0.85-1.67). For men, RRs for mobile phone use and tumors in the frontal lobe (1.13; 0.89-1.45), temporal lobe (1.13; 0.86-1.48), occipital lobe (1.47; 0.87-2.48) and other or unspecified brain regions (1.35; 1.05-1.75) were above 1. (Table 1, Table 2, Table 7)

Schuz et al. (2009) [98] also looked at central nervous system diseases in this same cohort. They looked for hospital contacts for migraine (RR 1.2, 1.1-1.3), vertigo (1.1, 1.1-1.2), alzheimer's (0.7 , 0.6-0.9), vascular dementia (ns), other dementia (0.7, 0.6-0.8), Parkinson (0.8, 0.7-0.9), ALS (ns), MS (ns), epilepsy in men (0.7, 0.7-0.7) and women (ns).

The biggest concern with all these studies [94, 96, 98, 99] are the various sources of misclassification that could be differential and/or non-differential. By their own count, 303,326 phone contracts could not be assigned to specific users and were classified into the non-user category. In addition, a member of the cohort may have been the owner of the account but not the primary user of the cellular phone (e.g. parents or spouses paying for the account). Using information from a separate case-control study [49], it was estimated that 16% of the non-users could have been frequent users; this was used to suggest the potential impact of this bias on the overall RRs will be low; no sensitivity analysis was provided. No phone data past 1995 was used for any of these analyses. According to the World Bank (2020) [100], there were 15.714 subscriptions to mobile phones per 100 people in Denmark in 1995 against a population of 5,233,373 [101]. To compare, 723,421 subscriptions in Denmark from 1982 to 1995 would be 13.82 per 100 people (very close to the World Bank numbers). By 2002, when the Schuz et al. (2006) [94] follow-up ended, there were 83.341 subscriptions per 100 people (5.3x increase) and by 2007 when Frei et al. (2011) [96] follow-up ended, there were 115.322 per 100 people (7.3x increase); in 2018, there are 125.119 subscriptions per 100 people in Denmark. Thus, of the 1853 male and 1455 female non-subscribers who had gliomas, most of them will have had subscriptions of some sort by 2007. Hence, the exposure misclassification is extreme with many cellular phone users in the non-subscription category who are undoubtedly using mobile phones. Finally, in the **Frei et al (2011)** [96] update, the use of the CANULI database required dropping all cell phone users below the age of 30 before 1995 which appears to be the 54,350 subscribers they lost; hence the youngest phone users before 1995 were excluded from the study.

Benson et al. (2013) [102] used data from the Million Women Study (MWS; for details, see [103, 104]) to evaluate the linkage between brain tumors and mobile phone use. Researchers recruited 1.3 million middle-aged women in the UK into the MWS during the period of 1996-2001. Women completed an initial survey on lifestyle factors, sociodemographic factors and medical history and are resurveyed every 3-4 years. Questions on mobile phone use were asked in 1999-2005 and again in 2009. Information about incident cases of brain tumors were obtained through linkage to Hospital Episode Statistics in England and Scottish Morbidity Records. Of the 866,525 women who answered the questionnaire between 1999 and 2005, numerous women were excluded from the analysis (14,387 got a questionnaire without cell phone usage, 11,981 did not answer the cell phone usage question, 48,531 had CNS tumors at baseline and 6 had a genetic predisposition to get neurological tumors); eventually leaving 791,710 women in the study. Average follow-up time was 7 years (follow-up was through December 31, 2009 except for 1 region where the date was December 31, 2008). Cell phone usage was assessed with two questions: 1) About how often do you use a mobile phone? Never/less than once a day/every day; 2) For how long have you used one? Responses to mobile phone usage questions in 2009 were used to assess the repeatability of earlier questions for the 31,110 women who answered both; however, the questions were different and consistency is not easy to assess. Approximately half of those who reported no use of a mobile phone in the first survey reported use in 2009. There were a number of demographic differences between mobile phone users and non users, including age, affluence, exercise, alcohol and smoking. In addition, the phone users saw less incident cancers (6.05%) than did non-users (7.32%) during the follow-up period. In total, there were 571 gliomas in this cohort. Risk ratios (RRs) for phone use were ever/never 0.91 (0.76-1.08), daily use 0.80 (0.56-1.14), <5 years 0.93 (0.71-1.21), 5-9 years 0.92 (0.75-1.13) and 10+ years of use 0.78 (0.55-1.10) (all adjusted for socioeconomic status, region, age (in 3-year groupings), height, BMI, alcohol intake, exercise and hormone therapy). In a letter responding to a letter by **de Vocht (2014)** [105], **Benson et al. (2014)** [106] updated their follow-up to 2011 but did not update cellular phone usage (still relying on the 1999-2005 response) and saw the RR for glioma for ever/never users of 0.86 (0.75-0.99). Note that with 7 years average follow-up, they saw 571 gliomas or 82/year but adding 2010 and 2011 increased the gliomas by over 100 per year. The main limitations of this study are the rapidly changing exposures to mobile phones and the short follow-up period. Both of these factors likely pushed the results toward the null. In essence, this study creates considerable challenges in terms of misclassification of exposure. For example, a case answering the question in 2005 with 1 year of usage would have 6 years of exposure. In contrast, a woman answering in 1999 with no cell phone usage who then gets a phone in 2000 has 10 years of use but is considered a non-user. This problem is exacerbated by the rapid increase in cellular phone usage in the UK during this period. Cellular phone usage in the UK increased dramatically during the actual study period as well as the recruiting period with rates per 100 people of 9.901 (1995), 12.473 (1996), 78.281 (2001), 108.598 (2005) and 121.73 (2009) [107] so some of the cases with no exposure are likely to have been exposed. They attempted to address these issues by excluding women who reported phone use in 1999-2000 since many of these will have changed their status but this discards the longest exposed individuals and removed 73 glioma patients with cellular phone usage (21.8%). In addition, the fact that the use of a cellular phone is associated with a significant reduction in all invasive neoplasms (e.g. ever use 0.97 [0.95-0.99]) could indicate a difference between the groups that is not being addressed in the analysis. (Table 1, Table 2)

4.1.2 Studies in Children

Elliott et al. (2010) [108] conducted a case-control study of cancers in children aged 0-4 in Great Britain looking at a linkage to mobile phone base stations. Cases were all registered children with cancer in 1999-2001 (1926 cases) and four controls for each case were chosen from the national birth registry matched by sex and date of birth. Birth addresses (or approximate addresses) were needed for each case and each control leaving a total of 1397 cases and 5588 controls. Three exposure metrics were used, distance from the nearest mobile phone base station, total output from all base stations within 700 meters, and a modeled power density (dBm) from all base stations within 1400 meters of the birth address (modeling was based upon surveys and then validated against later additional survey data). Of the 1397 cases, there were 251 brain cancers (1004 controls). None of the mean exposures for any of the three metrics were different between cases and controls. ORs were very close to 1 for all exposure metrics when exposure was broken into tertiles and the referent group was the first tertile. Similar results were seen in an analysis using the continuous exposure measure directly. The same patterns were true for all cancers and leukemias. (Table 8)

The CEFALO study (**Aydin et al. (2012)** [109]) is an international case-control study conducted in Denmark, Norway, Sweden and Switzerland of children and adolescents aged 7-19 years at time of diagnosis of a brain cancer. Cases had brain tumors with a specific ICD-10 classification and were identified by a combination of factors. Controls were matched on year and month of birth or just year of birth (Norway) with two cases per control. The study included 352 cases (83.2% response) and 646 controls (71.1% response); 213 of the cases had gliomas. Exposure was obtained by personal interviews with mobile phone use 6 months prior to diagnosis excluded from the analyses. Cases were asked for permission to access usage data from mobile phone operators. In Denmark and Sweden, data covered the entire period of usage whereas in Switzerland, data was only kept for 6 months so data were only available for after diagnosis; data from providers in Norway was not obtained. The OR for regular use (one call per week for at least 6 months) versus not was 1.36 (0.92-2.02). All ORs for time since first use were above 1 (1.35 (0.89-2.04) for <3.3 years, 1.47 (0.87-2.49) for 3.3-5.0 years, 1.26 (0.70-2.28) for > 5 years). Similar patterns were seen for cumulative duration of subscriptions (≤2.7 years, 1.34 [0.89-2.01]; 2.8-4 years, 1.45 [0.83-2.54]; >4 years, 1.58 [0.86-2.91]) , cumulative duration of calls (≤35 hours, 1.33 [0.89-2.01]; 36-144 hours, 1.44 [0.85-2.44]; >144 hours, 1.55 [0.86-2.82]) and cumulative number of calls (≤936 calls, 1.34 [0.89-2.02]; 937-2638 calls, 1.47 [0.86-2.51]; >2638 calls, 1.42 [0.79-2.53]). Stratifying the analysis for only gliomas yielded an OR of 1.14 (0.66-1.97) but only included 192 cases (it appears they excluded the 21 ependymomas even though these are gliomas). When they analyzed brain tumors using the operator-recorded data (35% of cases, 34% of controls), they saw a significant trend for time since first subscription (p=0.001) with the highest exposure group (>2.8 years) having a statistically significant OR of 2.15 (1.07-4.29). The same analysis using self-reported use had a trend test with p=0.22 and an OR in the highest exposure class of 1.47 (0.81-2.67). Other exposure metrics saw generally higher ORs using the operator-recorded use data than self-reported use; this is likely due to some degree of differential exposure misclassification since a study showed cases overestimated their numbers of calls (9%) and duration of calls (52%) much less than controls (34% and 163% respectively) [110]. The OR for ipsilateral use (1.74, 0.91-3.33) was not larger than that for contralateral use (2.07, 0.95-4.52), although the definition used for ipsilateral and contralateral was unique to this study [111]. For ipsilateral and contralateral use, exposure-response relationships were seen for all exposure measures and the highest exposure groups had the biggest ORs, many statistically significant. The major strengths of this study include the participation rates and the exposure information. The major weaknesses include a failure to analyze all gliomas and to do the ipsilateral analysis and operator-generated usage on the gliomas alone. There were other criticisms of this paper [112]. (Table 8)

Li et al. (2012) [113] conducted a population-based case-control study of incident cases of all cancers in Taiwan in children and adolescents <15 years of age between 2003 and 2007. Thirty controls were randomly selected for each case and matched on year of birth. The annual power density (APD; wattwatt-year/km^2) for each township was calculated from the 71,185 mobile phone base stations in Taiwan. Exposure was calculated as the average APD five years prior to diagnosis for cases and prior to July 1 for the controls in the year their matched case was admitted. For brain tumors there were 394 cases and 11,820 controls. OR for above median versus below median exposure was 1.09 (0.88-1.36) for the crude estimate and 1.14 (0.83-1.55) for the adjusted estimate (calendar year, age, gender, high-voltage transmission line, and urbanization of township). When the exposures were divided into tertiles, there was an indication of a trend (crude: 1.01 [0.84-1.42] T2, 1.09 [0.77-1.32] T3; adjusted: 1.03 [0.73-1.45] T2, 1.14 [0.70-1.85] T3), but no test for trend was used. The major limitation of this study is that the exposure metric does not pertain to the individual's exposure, but exposure to anyone in the township. Nearness to a tower, use of a cellular telephone, and other sources of RF that might have been related to disease incidence were not assessed. Thus, this study is closer to using an ecological exposure measurement than an individual personal exposure measurement. (Table 8)

Feltbower et al. (2014) [114] conducted a pilot case-control study of children and young adults ages 0-24 in two UK cancer treatment centers. Eligible cases were 0-24 years of age presenting with a diagnosis of intracranial tumor during an unspecified period. At one center, cases were matched by age and sex with a target of 2 controls per case and randomly selected from the general practice. At the second center, 3 friend controls were envisioned but the researchers were unable to attain any controls. Eventually, they were able to interview 49 cases (52% response) and 78 controls (32% response). The study was designed to be compatible with the CEFALO study [109]. The OR for brain cancer and having spoken on a mobile phone more than 20 times was 0.9 (0.2-3.3). The main weaknesses of this study are its size, response rate, and failure to get controls from the second center. (Table 8)

4.1.3 Discussion

The strongest evidence for an effect of RF on the risks of glioma come from the case-control studies. Case-control studies are designed to compare the exposure characteristics of cases (people who have or have had a glioma) against a collection of controls (people without a history of gliomas). In evaluating the results from case-control studies, researchers must consider two possible sources of bias; selection bias and recall bias. Selection or participation bias occurs when the people who are selected to be a part of the study (both cases and controls) are not willing to participate and that participation is related to both the status of the person (case versus control) and to the exposure (cellular phones) being investigated. For example, if participants that do not use a cellular phone are less willing to participate than participants who do use a cellular phone and that controls are less likely to participate than cases, this can reduce the odds ratio[1] (OR) and hide a potential risk.

Case-control studies rely on measures of exposure that are generally obtained through a questionnaire administered to both the cases and the controls about their past exposures. Because they are recalling past exposures, there is a possibility that this recall may be linked in some way to their status as a case or a control. This is recall bias. For example, if cases are more likely to say they have used a cellular phone than controls or they are more likely to overestimate their cellular phone usage, this could increase the ORs and lead to an overestimation of the risk from cellular phone use. The recall must be different for the cases than the controls for this to cause a bias; errors in recalling past exposures that are similar for both cases and controls would not be recall bias.

Cohort studies generally do not have these two problems since they are asked about their exposure prior to getting the disease of interest. Cohort studies are usually aimed at identifying causes for disease in a large population of people who are followed over time. As the diseases appear in the population, an analysis is done to evaluate the risk ratio[2] (RR) in order to find exposures that are associated with the disease. Exposure is generally determined using a questionnaire administered during the course of the study where participants are asked about their exposures. Disease status (e.g. presence or absence of a glioma) is usually determined through periodic evaluations of cancer registries and publication of the results; thus the study has a baseline date (the date a participant enters into the study) and a follow-up date (the last date of update of the cancer registry or the date the participant got the tumor or the date the participant left the study). In evaluating the results from cohort studies, researchers must consider a different source of bias; exposure

---

[1] The odds ratio (OR) is calculated as the proportion of exposed cases with disease to exposed controls divided by the proportion of non-exposed cases to non-exposed controls. For rare diseases, this value approximates the population risk ratio (PRR) which is the probability of having the disease in exposed individuals divided by the probability of having the disease in non-exposed individuals. If the PRR is 1, then there is no difference in the probability of having the disease regardless of your exposure. Values of PRR greater than 1 imply the risk is higher in the exposed population. Because the OR is an estimate of the PRR for rare diseases, it is usually accompanied by a 95% confidence interval that describes the probable range of the estimate. If the OR is greater than 1, then the exposure is associated with the disease. If the lower 95% confidence bound for the OR is greater than 1, this is typically used to say the association is statistically significant.

[2] The rate ratio (RR) is estimated as the incidence in the exposed population divided by the incidence in the unexposed population. Incidence is calculated as the number of events in a fixed period of time divided by the person years at risk. Unlike the OR, the RR does not require the assumption of a rare disease to serve as a good estimate of the population risk ratio (PRR). Like the OR, RR>1 implies an association between the disease and the exposure.

misclassification. Exposure misclassification occurs when the exposure for participants is incorrectly applied. For example, if a participant is asked on Tuesday about their cellular phone use and they do not use a cellular phone, they would be classified as a non-user. If on Wednesday, they go to the store and purchase a phone, they are now a user, but if they do not get asked again about their use prior to the follow-up date, they would be misclassified in any evaluations. Non-differential exposure misclassification occurs when the probability of an error in determining whether an individual is exposed or not is the same for both those with the disease and for those without the disease. Non-differential exposure misclassification generally results in RRs that are closer to 1 than the true underlying risk would imply and can hide risks that are really there. Differential exposure misclassification occurs when there is a difference in the exposure misclassification between those with the disease and those without. Depending on the direction of the misclassification relative to disease status, this can either hide risks or inflate risks. For example, if those with the disease are more likely to be misclassified as non-exposed, the estimated RRs will be smaller than they should be and this would result in a reduced estimate of the risk.

Finally, one other problem to be carefully considered is confounding. Confounding occurs when exposure is correlated with another factor that is also associated with the disease of interest. For example, if age is associated with the incidence of gliomas and is also correlated with cellular phone usage, failure to recognize this potential confounding could lead to an association between cell phone usage and the incidence of gliomas that is spurious. To avoid this, researchers, when evaluating their data, will "adjust" the analysis for other potential confounders. Thus, in evaluating the findings from these studies, it is important to evaluate what adjustments were made for potential confounders in the analysis. This problem can affect both case-control studies and cohort studies.

In evaluating the epidemiological evidence, there are three areas that need to be carefully explored: consistency of the association, the existence of an exposure-response relationship (definitions to follow), and the strength of the association.

4.1.3.1 Consistency of the Association

I will focus on the main studies listed in Table 1. All of these studies did a reasonable job of addressing confounders in their analyses and so this problem will not be discussed further. First, we should consider timing of the study. According to the **World Bank** [115], 0.001% of people globally had subscriptions to mobile phones in 1980. By 1990, that was 0.2% and by 2000 it was 12%. In the US, by 1990, 2% of people had subscriptions and by 2000, 39% had cellular phones. Thus, for studies in the 1990s, we are looking at a rare exposure and trying to associate it with a rare disease (gliomas) and probably with very little time from the beginning of exposure to disease onset. Thus, it is unlikely that studies like **Hardell et al. (1999)** [85], **Muscat et al. (2000)** [40], **Inskip et al. (2001)** [44], and **Auvinen et al. (2002)** [45] would show much of an association. And that is basically the case, with these studies producing ORs of approximately 1.0 except for **Auvinen et al. (2002)** [45] with an OR of 1.5 (1.0-2.4). Thus, the later studies are more likely to show an effect if one exists than are the earlier studies and these should be given greater weight.

The size of a study will also matter since studies with greater numbers of cases and controls (especially exposed cases) will generally have smaller confidence bounds and have a greater chance of seeing an effect if one exists. Thus, the studies by **Gousias et al. (2009)** [46] and **Baldi et al. (2011)** [89] will carry less weight in an overall evaluation.

There are also studies where the referent group was "never used a mobile phone" versus studies where the referent group was "not a regular user of mobile phones" defined by different measures. Less weight should be given to studies with comparisons to "never used" simply because the "ever used" group could include people who used a phone only a few times.

Given these caveats, there are 4 case-control studies that should carry the greatest weight; **Interphone (2010)** [48], **Coureau et al. (2014)** [90], **Hardell et al. (2015)** [88] and **Yoon et al. (2015)** [93]. Three of these studies show ORs >1 for regular use of a cellular phone with only one showing a significantly increased OR (**Hardell et al. (2015)** [88], 1.3 (1.1-1.6)).

The largest study, **Interphone (2010)**, has an OR<1 and more cases and controls than the other three studies combined. The ORs also did not increase with increasing duration of the use of a mobile phone (Table 1). This study used cases that were both living and, by proxy information, those who had died before interview. However, in the Interphone study there was some degree of participation bias [48, 116] that could have resulted in a reduction of the ORs by as much as 10% according to some analyses [74, 116]. For example, just looking at the cases and controls from Canada in the Interphone study, the OR for regular use of a cellular phone went from 1.0 (0.7-1.5) to 1.1 (1.0-1.2) when this bias was theoretically corrected [116]. Applying this same bias correction to the Interphone study yields an OR of 0.9, still below 1. Another correction one could use to account for participation bias, and to some degree recall bias, is to use the lowest category of usage as the reference category rather than the non-regular user category. When this was done for the Interphone study, using the lowest duration of use as the reference group, all longer durations were significantly greater that 1.0 (Table 2). Analyses of recall bias in the Interphone study showed very little impact of recall bias on the evaluation of regular usage [74, 116].

The studies demonstrating the greatest ORs for regular use are the studies that went into the pooled analysis by **Hardell et al. (2015)** [88]. Their pooled study showed an overall OR of 1.3 (1.1-1.6) for regular use. In addition, all of the 5-year groupings of duration of use were greater than 1 and all usage longer than 5-years was significantly greater than 1 (Table 2). Only living cases were included. Their response rate was high enough that participation bias is unlikely to have lowered the OR values. It is possible that participation bias could have occurred from the use of only live cases, but in a separate analysis from a subset of the pooled studies, they saw no important differences between their analyses using live cases when compared to analyses using only deceased cases. On the other hand, recall bias could have increased the ORs. In one of the original case-control studies [117] used in their pooled analysis, they evaluated this issue and saw little indication of recall bias. In addition, in their pooled analysis, they used meningioma cases as the reference group since they were likely to have the same recall bias as the glioma cases if recall bias was a problem. The OR from the population-based reference group was 1.3 (1.1-1.6) and dropped slightly to 1.2 (0.97-1.5) with the meningioma reference group. It is unlikely recall bias explains these results.

Spinelli et al. (2010) [47] is also a very small study, but they provided no information on ever versus never use of mobile phones.

Coureau et al. (2014) [90] is about 12 times smaller than the Interphone study and about 7 times smaller than **Hardell et al. (2015)** [88]. Their evaluation showed an overall OR for regular users of 1.24 (0.86-1.77) which rose slightly to 1.33 (0.89-1.98) if proxies are removed. Duration of use was weakly associated with duration of cellular phone use but had the highest OR (1.61 [0.85-3.09]) in the longest duration group (≥10 years) (Table 2). This study used cases that were both living and, by proxy information, those who had died before interview. This study had a lower participation rate than the other two studies and a large difference in participation between cases (66%) and controls (45%). They did not have a questionnaire for non-participants so there is no information on whether participation bias is a problem in this study. Exposure from mobile phones was done by interview using a standardized questionnaire which limits mistakes, but does nothing to control for potential recall bias. The fact that ORs for analyses with proxies versus those without proxies gave equivalent results helps to reduce the possibility of recall bias, but the number of proxy respondents was small.

Yoon et al. (2015) [93] has about twice as many exposed cases as **Coureau et al. (2014)** [90]. The OR for regular use was 1.17 (0.63-2.14) dropping to 0.94 (0.46-1.89) if proxy responders are removed. The OR for duration of use was >1 for all categories but showed no obvious pattern and dropped slightly when proxies were removed. The participation rates in this study were very low (32% cases, 27% controls) mostly due to cases refusing to participate or not participating due to excess pain. Participation bias and recall bias are certainly possible from this study.

One way in which to evaluate the consistency of these findings across the various studies is by means of a meta-analysis. A meta-analysis is a technique of synthesizing research results by using various statistical methods to retrieve, select, and combine results from previous separate but related studies. There have been numerous meta-analyses on the relationship between cell phone use and gliomas [118-125]. The three most recent studies are worth a quick review. **Roosli et al. (2019)** [118] explored the risks of glioma using the two cohort studies [96, 102] and 10 case-control studies [40, 44, 45, 47, 48, 85, 88-90, 93] based upon an inclusion criteria of 1) a clearly defined source population, 2a) provide a comparison of ever versus never use of a mobile phone (they also included regular use) and/or 2b) allow for an evaluation of long-term use (≥10 years of use before glioma diagnosis) and 3) where there are multiple publications on the same data or subsets of the same data, they included the most recent comprehensive analysis. Where there were multiple publications of subgroups of studies (e.g. Interphone), they did sensitivity analyses to examine the impact of using the subgroups rather than the pooled publications. Meta-estimates of glioma risks (mRRs) were calculated using a random-effects model using the DerSimonian and Laird method using Stata (version 11.2, Stata Corp, College Station, Texas). Unless noted otherwise, all of the meta-analyses used the same method of a random-effects model and the DerSimonian and Laird method).

The main analysis from **Roosli et al. (2019)** [118] is shown in their Figure 1 and give the mRRs for the analyses of studies showing ORs for ≥10 years exposure. For the case-control studies, they get an mRR of 1.30 (0.90-1.87). For the Cohort studies, they show an mRR of 0.92 (0.72, 1.16) and for all studies combined they get 1.11 (0.85-1.46). Entering their numbers into Stata (v 16.2 for MAC), I am able to reproduce their mRRs, however, they had to first calculate an mRR for ≥10 years in the study by Hardell et al. (2015) [88] by combining results from multiple 5-year categories. They list this combination as giving an mRR for ≥10 years for that study of 1.69 (1.40-2.03) whereas when I do the same analysis, I get 1.81 (1.35-2.43). The only way I was able to achieve the same results as **Roosli et al. (2019)** [118] for the mRR was to use a fixed-effects model rather than a random-effects model (this appears to be a mistake in the paper). They also did a meta-analysis of ever versus never use for all 10 case-control studies (1.03 [0.86-1.22]) and the cohort studies (0.97 [0.82-1.15]) with a combined mRR of 1.00 (0.89-1.13). They also conducted a cumulative meta-analysis of the studies with ≥10 years of use splitting the Hardell group studies into those from 1997-2003 and 2007-2009 yielding a slightly higher mRR (1.24 [0.93-1.66]) for all studies combined. They also did several other analyses of ever versus never use with no appreciable changes in the results. One problem with these meta-analyses is that they give very little weight to the largest studies. For example, in their analysis of the 12 ever versus never studies, **The Interphone (2010)** [48] study with 1666 exposed cases got a relative weight of 13%, **Hardell et al. (2015)** [88] with 945 exposed cases got a relative weight of 11.6% and the remaining studies with a total of 1586 exposed cases got a relative weight of >75%. In addition, all of these analyses showed highly significant heterogeneity. Roosli et al. (2019) [118] did not consider laterality or tumor location in the brain.

Wang et al. (2018) [119] did a meta-analysis like that done by **Roosli et al. (2019)** [118] for ever versus never use, but did not include the **Spinelli et al. (2010)** [47] study (no reason given) and instead of using all malignant brain tumors from **Muscat et al. (2000)** [40], they included separate ORs for astrocytic tumors (0.80 [0.50-1.20]) and oligodendrogliomas and mixed gliomas (0.90 [0.40-2.10]). They also included wireless telephones from **Hardell et al. (2015)** [88] in their analyses. Their analysis resulted in an mRR of 1.03 (0.92-1.16). They also did meta-analyses on the data for 0-5 years (0.92 [0.77-1.09]), 5-10 years (1.07 [0.88-1.30]) and ≥10 years (1.33 [1.05-1.67]). Their ≥10 years category was done differently than **Roosli et al. (2019)** [118] in that they did not include **Yoon et al. (2015)** [93] and the 4 exposure categories for **Hardell et al. (2015)** [88] were entered directly into the analysis rather than being pooled first. All of these analyses showed significant heterogeneity which they said was reduced by removing either the Interphone study or the study by **Hardell et al. (2015)** [88]. For ipsilateral tumors and ever versus never use, they saw an mRR of 1.26 (0.87-1.84) in comparison to contralateral use that showed an mRR of 1.10 (0.85-1.42). Finally, evaluating gliomas located in the temporal lobe, again for ever versus never use, they saw an mRR of 1.61 (0.78-3.33) [Note that in the text of the manuscript rather than their table, they list this mRR as 0.93 (0.69-1.24); I was able to verify the mRR of 1.61 but could not find a reasoning behind the number in the text]. The relative weights for the individual studies also fail to match the sample sizes in these evaluations.

Yang et al. (2017) [120] also performed a meta-analysis on some of the studies included in this review. Their analysis excluded both the **Hardell et al. (2015)** [88] pooled analysis and the **Interphone (2010)** [48] pooled analysis. Instead, they included the **Hardell et al. (2011)** [126] study that included the pooled analysis of the 1997-2003 studies with the inclusion of deceased cases and individual Interphone studies from separate countries [49, 52, 54, 55, 59, 61] or a pooled analysis from 5 countries [64]. For ever versus never use, they saw an mRR of 0.98 (0.88-1.10) and for ≥10 years duration of use, the mRR was 1.44 (1.08-1.91); both evaluations showed substantial heterogeneity. For ipsilateral use and ever/never exposures, the mRR was 0.97 (0.88-1.06) whereas for contralateral use it was 0.75 (0.65-0.87) with marginal heterogeneity. For ≥10 years use, the ipsilateral mRR was 1.46 (1.12-1.92) and contralateral use was 1.12 (0.81-1.55) with no heterogeneity. The studies on laterality did not include the study by **Hardell et al. (2011)** [126] for low-grade (1.11 [0.87-1.42] ever/never, 2.22 [1.69-2.92] ≥10 years) and high grade (0.82 [0.68-0.99] ever/never; 1.16 [0.85-1.59] ≥10 years) gliomas.

The remaining meta-analyses are older and use fewer and fewer of the individual studies. One meta-analysis worth mentioning is the one done by **Hardell et al. (2013)** [127] directly comparing the results of **Hardell et al. (2011)** [128] with the results from the pooled **Interphone (2010)** [48] study. For a latency of ≥10 years, the saw the following mRRs: all users 1.48 (0.65-3.35); ipsilateral 1.84 (0.80-4.25); contralateral 1.23 (0.40-3.73); temporal lobe 1.71 (1.04-2.81). For a cumulative use ≥1640 hours, they saw the following mRRs: all users 1.74 (1.07-2.83); ipsilateral 2.29 (1.56-3.37); contralateral 1.52 (0.90-2.57); temporal lobe 2.06 (1.34-3.17). An important point of this report is that the **Interphone (2010)** [48] study included adults 30-59 years of age and **Hardell et al. (2011)** [128] extracted the same group from their 1997-2003 pooled analysis [86] and adjusted the exposure groupings to match the Interphone groupings. They did not present these numbers in their meta-analysis, but that can be done. The results of the same random-effects modeling as done by **Hardell et al. (2011)** [128] yields the following results: ≥10 years 1.30 (0.72-2.33); ≥1640 hours 1.48 (1.13-1.92); ≥1640 hours ipsilateral 2.03 (1.37-3.00); ≥1640 hours contralateral 1.32 (0.76-2.28).

It is clear from these numerous meta analyses, that the choice of which studies to use, how to enter the multiple studies by Hardell et al. and whether to use the pooled analysis from the Interphone study or some of the single analyses can have an impact on the final values. To provide a better view of the results, Figure 1 is a forest plot of all of the ORs from individual publications that evaluated regular use versus minimal or never use or ever use versus never use (if both were given in a study, regular use is shown). The column labeled "Study" provides the reference to the publication and the years in which cases and controls were collected for case control studies and the years when phone use information was collected for cohort studies and the year in which follow-up ended. Some studies are pooled evaluations of multiple other studies, so the other studies are indented. For example, the **Interphone (2010)** [48] study (Study F) is the pooled analysis of studies from 13 countries. **Lahkola et al. (2007)** [64] (Study F3) is a pooled analysis of the data from 5 of those countries and **Christenson et al (2005)** [49] (Study F3a) is the publication for data from one of those 5 countries. The column labeled "RR" is the risk ratio (OR, RR or mRR) from the study, "Lower" and "Upper" are the lower and upper bound on a 95% confidence interval around the RR. The graphic on the right simply plots the RR as a square or diamond with the "whiskers" (blue line running through the box) showing the width of the 95% confidence interval. The vertical line passing through 1 represents no effect. If the box and both whiskers are to the right of this line (greater than 1) and not touching it, this finding is statistically significant with a positive effect; if they fall completely to the left of the vertical line (below 1), then the risk is significantly reduced. The blue boxes that are filled in are major studies, the blue boxes that are white in the middle are the sub-studies and the red diamonds are all meta-analyses.

The graphic in Figure 1 is very useful for examining these types of data in a single view. Looking just at the filled in blue blocks (Studies A,B,C,D,E,F,G,H,I,J,K,L), it is clear some studies (D, I) fall clearly above the vertical line and demonstrate statistically significant increased risk. One study (F) shows a significant reduction in risk. The remaining studies show increases (H, J, K) or decreases (A, B, E, G, L) or no risk (C). The question to be addressed is what is the overall tendency of these data? The meta-analyses address this issue. The first meta-analysis (Meta Analysis A,B,C,D,E,F,G,H,I,J,K,L) combines the information from all of the major studies to produce an mRR of 1.01 (0.92-1.11) for ever versus never exposure suggesting that all of the positives and negatives balance out to give no overall effect. This meta-analysis also shows these studies are very different (Homogeneity Test: p=0.01) which suggests the combination is not accounting for all of the variability in the RRs. However, as mentioned earlier, the newer, larger studies represent longer exposures, so I have also done meta-analyses on four large, recent case-control studies (F,H,I,J) and the two cohort studies (K,L) which should carry the greatest weight in any decision. Combining the four case-control studies (Meta Analysis F,H,I,J) results in a mRR of 1.09 (0.8-1.49), a slight increase in risk from the use of a mobile phone, but still heterogenous across studies. The combined cohort studies yield a mRR of 0.97 (0.74-1.27) suggesting no risk, and no heterogeneity (p=0.84). Combining the 4 case-control studies and the 2 cohort studies (Meta Analysis F,H,I,J,K,L) yields an mRR of 1.03 (0.86-1.24) again suggesting no risk but with significant heterogeneity (p=0.00).

As mentioned earlier, the Interphone study did an alternate set of analyses where the referent group was different depending upon the exposure metric being used (Appendix 2 Table, **Interphone (2010)**). It is possible to use meta-analysis to combine these results to get a pseudo regular/not mRR for each exposure metric[3]. The rows labelled F6, F7 and F8 are the mRR values for these meta-analyses: F6 is an estimate of ≥2years since start of regular use compared to 1-2 years of regular use [mRR 1.75 (1.40-2.18)], F7 is ≥5 hours of cumulative hands-free use compared to <5 hours [mRR 1.16 (1.00-1.35)], and F8 compares ≥1500 cumulative calls to <1500 cumulative calls [mRR 1.12 (0.96-1.30)]. To evaluate the sensitivity of the meta-analyses to the use of this alternative set of reference groups, I applied the least significant evaluation (F8) to the meta-analyses as a replacement for the Interphone study value (F). For the full analysis (Meta Analysis A,B,C,D,E,F8,G,H,I,J,K,L), the mRR becomes almost statistically significant; mRR 1.06 (0.98-1.15). Using just the larger and recent case-control studies (Meta Analysis F8,H,I,J), the mRR is significant [mRR 1.19 (1.07-1.33)] as is the combination of these case-control studies with the cohort studies [mRR 1.12 (1.01-1.24)]. None of these meta-analyses substituting F8 for F show significant heterogeneity. Thus, the meta-analysis is highly sensitive to the use of the reference group for the Interphone study.

Figure 2 is a forest plot of all of the ORs from individual publications that reported on duration of use ≥8 years or more. There are 6 studies; 5 of these studies show groupings of 1-4 years, 5-9 years and ≥10 years and one study with groupings of 1-5 years, 5-8 years and ≥8 years. For the study by **Hardell et al. (2015)** [88], groupings of 10-14, 15-19, 20-24 and ≥25 years were combined by meta-analysis to get a single mRR for ≥10 years. For **Frei et al. (2011)** [96], individual male and female RRs were combined by meta-analysis to get a single mRR for males and females combined. There are 4 groups of meta-analyses each with three separate meta-analyses for 1-4 years, 5-9 years and ≥10 years (combined with 1-<5 years, 5-8 years and ≥8 years respectively for **Yoon et al. (2015)** [93]). The four groups are case-control studies, case-control studies and cohort studies, then the same two groups substituting the original analysis in the Interphone study with their alternative analysis using 1-1.9 years as the referent group. A few things are noticeable in the Forest plot; with the exception of **Yoon et al. (2015)** (D), all of the case-control studies (A, B and C) show increasing ORs with increasing duration of use. The cohort studies (E and F) generally have decreasing RRs with increasing duration. In the meta-analyses, regardless of how the data are combined, there are increasing mRRs with increasing duration. The case-control studies generally show larger mRRs than the case-control and cohort studies combined and using the alternative referent group from the Interphone study yielded the largest mRRs with the highest 2 categories of duration being statistically significant for case-control studies using the alternate referent group.

The studies in adults are consistent.

Aydin et al. (2012) is the only study in children that looked at regular use of a mobile telephone and saw an OR of 1.36 (0.92-2.02). For years since first use, they saw ORs of 1.35 (0.89-2.04), 1.47 (0.87-2.49) and 1.26 (0.70-2.28) for lag times of ≤3.3 years, 3.3-5 years and >5 years respectively. When they used operator-recorded first use and lag times of ≤1.8 years, 1.8-2.8 years and >2.8 years, they saw a significant increasing risk (p=0.001) and ORs of 0.78 (0.43-1.40), 1.71 (0.85-3.44) and 2.15 (1.07-4.29) respectively. When they divided the tumors into gliomas or other tumors, they saw an OR for gliomas of 1.14 (0.66-1.97) and for other of 1.65 (0.93-2.93). They saw no

[3] To build this combination, a meta-analysis is done on all of the risk ratios for a specific exposure metric (e.g. 1-5 years, 5-10 years and ≥10 years latency). To check if this yields reasonable mRRs, meta-analyses were used to combined the various categories under the three exposure metrics in the cases where the referent group is non-regular users. There analysis yielded OR=0.81 (0.70-0.94) whereas doing a meta-analysis to get an equivalent estimate yielded mRR=0.84 (0.72-0.99) for latency years, mRR=0.82 (0.72-0.94) for cumulative hours and mRR=0.82 (0.75-0.90) for cumulative number of call.

relationship with the temporal lobe (1.00 (0.58-1.72). **Feltblower et al. (2014)** saw an OR of 0.9 (0.2-3.3) for young adults who used a mobile phone more than 20 times.

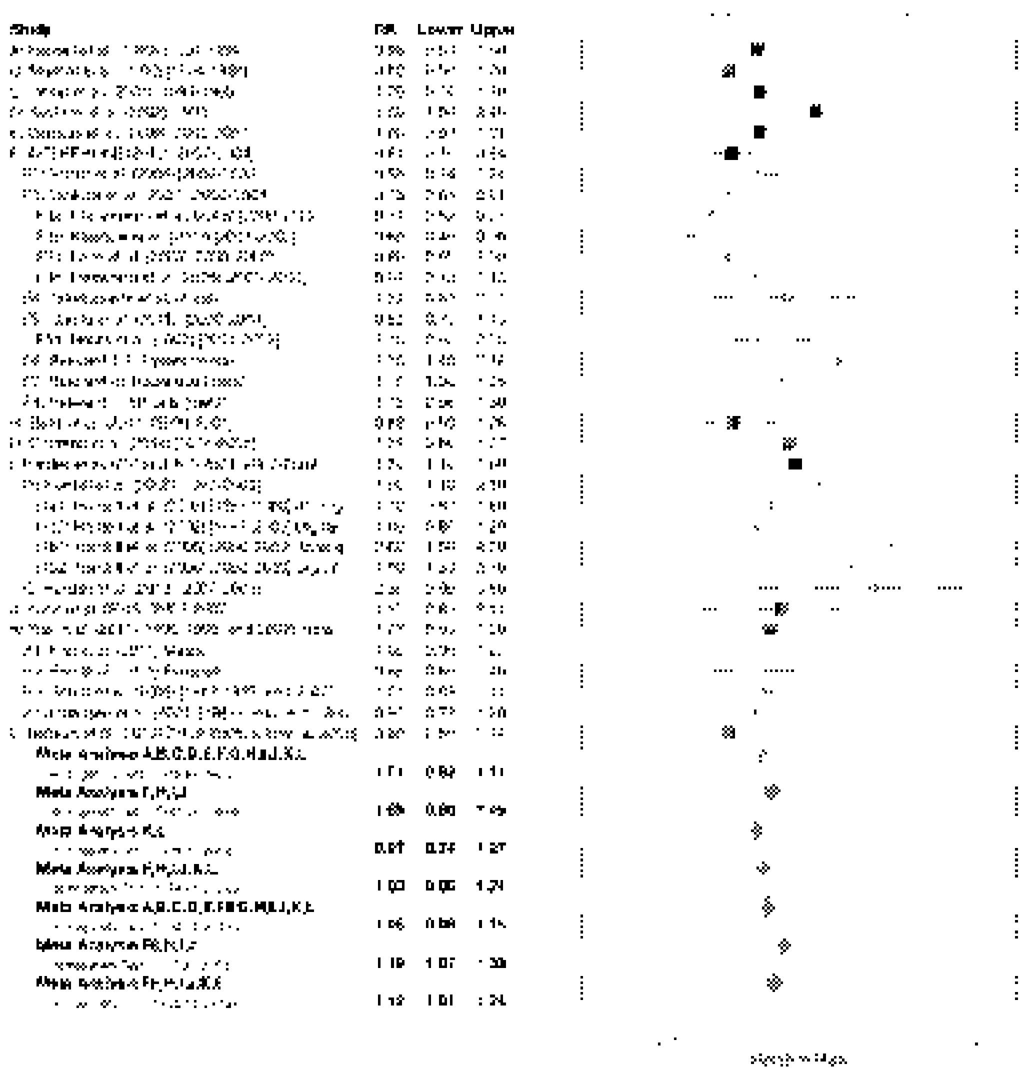

Figure 1: Forest plot and meta analyses of regular use or ever use of cellular telephones and the risk of glioma [studies with a solid blue square either single studies that stand alone or pooled studies that encompass numerous single studies; open squares are individual studies or smaller pooled studies; red diamonds are meta-analyses]*

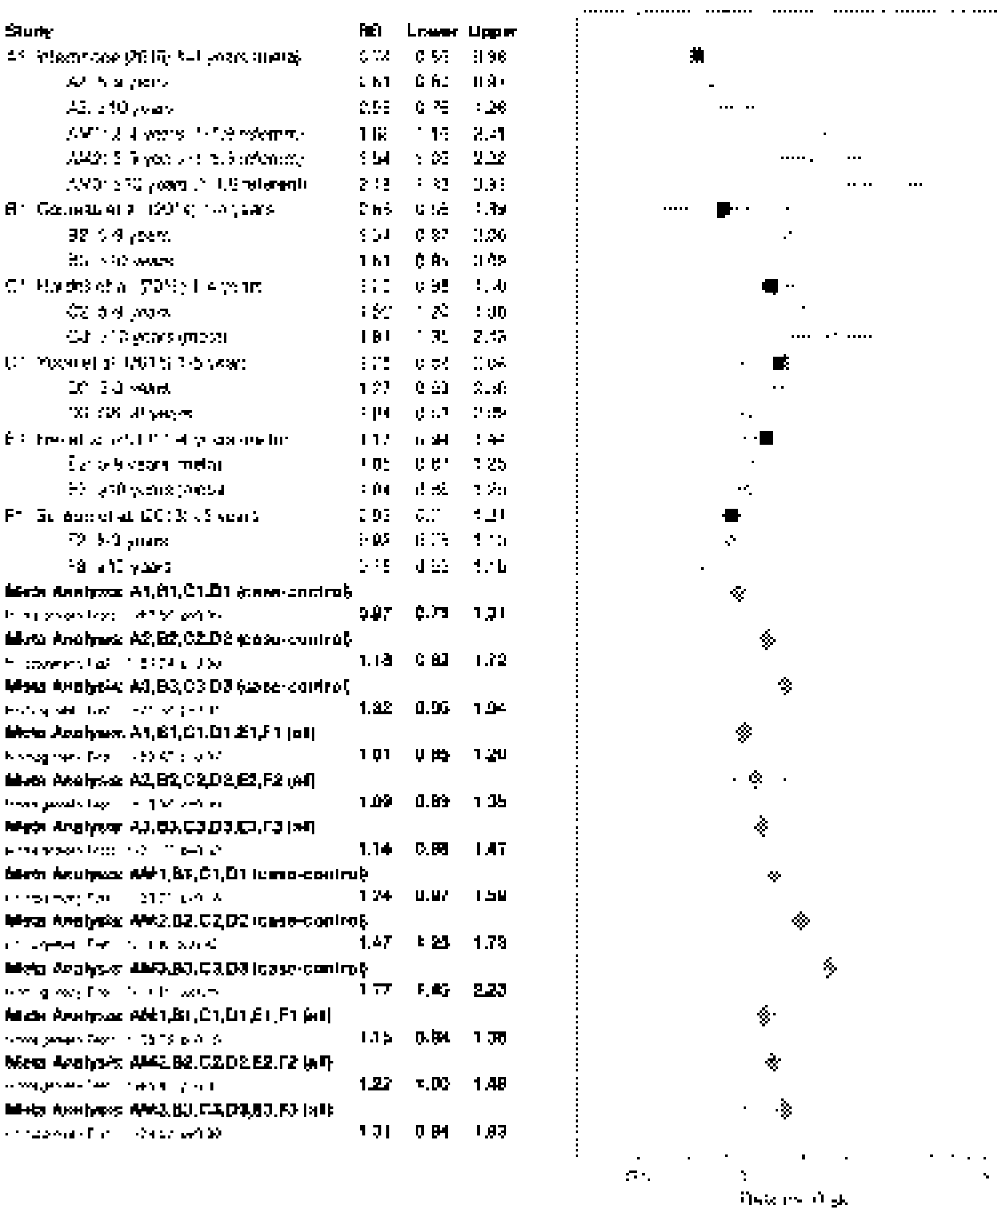
* - The column labeled "Study" provides the reference to the publication and the years in which cases and controls were collected for case control studies and the years when phone use information were collected for cohort studies and the year in which follow-up ended. Some studies are pooled evaluations of multiple other studies, so the other studies are indented. For example, the Interphone study (Study F) is the pooled analysis of studies from 13 countries. Lahkola et al (2007) (Study F3) is a pooled analysis of the data from 5 of those countries and Christensen et al (2005) (Study F3a) is the publication for data from one of these 5 countries. The column labeled "RR" is the risk ratio (OR, RR or mRR) from the study, "Lower" and "Upper" are the lower and upper bound on a 95% confidence interval around the RR. The graphic on the right simply plots the RR as a square or diamond with the "whiskers" (blue line running through the box) showing the width of the 95% confidence interval. The vertical line passing through 1 represents no effect. If the box and both whiskers are to the right of this line (greater than 1) and not touching it, this finding is statistically significant with a positive effect. If they fall completely to the left of the vertical line (below 1), then the risk is significantly reduced. The blue boxes that are filled in are major studies, the blue boxes that are white in the middle are the sub-studies and the red diamonds are all meta-analyses. "Homogeneity Test" provides the I^2 statistic and the p-value for the Q-test.



[illegible]: Forest plot and meta-analyses of duration of use of cellular telephones and the risk of glioma [studies with a solid blue square are either single studies that stand alone or pooled studies that encompass numerous single studies; open squares area second analysis from that same paper; red diamonds are meta-analyses, the columns and the figure are as in Figure 1].

[illegible]

The best measure for exposure-response relationships is the cumulative hours of use of a cellular telephone since it includes both the frequency of use and the duration of use. While duration of use is also a form of exposure-response, it is more likely that, similar to ionizing radiation, total accumulated exposure is related to the risk of glioma if a relationship exists. Table 8 provides the results for all of the epidemiology studies with estimates of the cumulative use of cellular phones.

Inskip et al. (2001) shows no consistent exposure-response and has all of the ORs below 1. **Spinelli et al. (2005)** show an increase in the OR for use of 48-432 cumulative hours, but this drops for ≥432 hours. In addition, their measure of cumulative hours is different from the remaining studies in that they calculated frequency of use based upon the number of hours allowed in the subscription rather than the actual usage as recounted by the user. This could lead to misclassification of exposure and may have affected the ORs. The **Interphone study (2010)** basically shows flat exposure-response for the entire study until the largest exposure category, that is significantly elevated in risk with an OR of 1.40 (1.03-1.89). Using greater than 0 but less than 5 hours as the referent group, they see higher ORs with a slight increasing pattern and again the highest exposure group significantly elevated. **Coureau et al. (2014)** saw a clearly increasing exposure-response pattern with ORs below 1 in the low exposure categories and becoming marginally significant in the second highest exposure group [1.78 (0.98-3.24)] and significant in the highest exposure category [2.89 (1.41-5.93)]. Excluding proxies did not change this pattern. **Hardell et al. (2015)** saw a clear pattern of increasing risk with increasing exposure with all of their categories statistically significant. They also did a regression resulting in an OR of 1.013 (1.009-1.017) per hundred cumulative hours of use with a p<0.0001. Finally, **Yoon et al. (2015)** saw a similar up-down pattern as **Spinelli et al. (2009)**, but with lower ORs and none of them significant.

It is not possible from the published results to find categories of exposure that match across the various studies in order to do a simple meta-analysis by category. However, it is possible to do a meta-regression where the exposure categories are turned into a single exposure and the meta-regression tests to see if the slope of the data from the various studies is increasing with exposure. In order to do this analysis, I set the exposure for each category equal to the center of the interval defined for the category (e.g., if the category is 512-1486 hours, the midpoint exposure is (512+1486)/2=999 hours). For Inskip et al. (2001), the last category is ≥100 hours and had 54 cases and ≥500 hours had 27, so I chose 500 for the highest exposure. For the remaining studies, it is not clear how to choose the exposure of the highest category. To follow the same pattern seen with **Inskip et al. (2001)**, I chose 5x the lower limit of the last category as the regression point for that category. **Hardell et al. (2015)** did a regression through their data and saw an OR of 1.013 (1.009-1.017) per 100 hours; doing a meta-regression using only the **Hardell et al. (2015)** data with the highest category dose set at 5x1486=7430 hours yields an mRR of 1.011 (1.005-1.018), similar to the result seen by **Hardell et al. (2015)**. A second dosing approach for the last category was to take the difference between the middle of the second largest category and the lower bound of that category and add it to the upper end of the second highest category to get the exposure for the highest category (e.g. if 512-1486 hours is the second highest category and the last category is ≥1486 hours, I set the center of the highest category as (512+1486)/2-512+1486=1973 hours). The exposures for all of the categories of the studies entering into the main meta-regression are shown in Table 9. The study results from **Spinelli et al. (2009)** are excluded from the meta-regression because of the difference in their exposure metric.

Table 10 provides the results of the meta-regression for the 5 case-control studies with duration of exposure where all of the ORs are a comparison against non-regular users. There is a significant association between exposure and risk with an mRR of 1.007 (1.002-1.012, p=0.004). Dropping the **Interphone (2010)** study from the meta-regression results in a highly significant trend (1.011 [1.005-1.017]; p<0.001), almost doubling of the risk, and reduced heterogeneity between the studies. In contrast, dropping the study by **Hardell et al. (2015)** reduces the risk by almost half

(1.004 [0.998-1.010; p=0.184) but the heterogeneity remains. Dropping any of the other studies has little impact on the findings. The alternate dosing strategy for the highest dose yielded the same pattern but mRRs that are roughly 3 times higher than those presented in Table 10 (not shown). (Table 10)

To examine the sensitivity of the analysis to the use of a different referent population in the Interphone study, their analysis using greater than 0 and <5 hours of cumulative exposure as the referent group was plugged into the same analysis. Table 11 provides the results of the meta-regression for the 5 case-control studies with duration of exposure using the alternative referent group. There is an increase in the mRR to 1.010 (1.006-1.014) per 100 hours of use. This fit demonstrated less heterogeneity with I^2=33.95. None of these results change substantially if any one study is dropped from the meta-regression. The alternative high dose yielded the same pattern but higher ORs per 100 hours (not shown). (Table 11)

There were other measures of exposure used in the various studies that are worth mentioning. **Inskip et al. (2001)** used average daily exposure and saw no exposure-response relationship (Table 4). **Coureau et al. (2014)** used average monthly exposure and saw a fairly clear exposure-response relationship (Table 4). **Inskip et al. (2001)** also considered the year that cellular telephone use began and again saw no exposure-response (Table 5). The **Interphone Study (2010)** considered cumulative use by years of duration of use (1-4 years, 5-9 years and ≥10 years). In each duration category, they saw the same pattern of flat exposure-response except for the highest cumulative exposure group that was increased in all categories. The shortest duration had the highest OR in the highest cumulative use category, but also had only 25 exposed cases with that much usage (to get greater than 1640 hours of usage in 4 years would require >1 hour of usage every day) (Table 5). **Coureau et al. (2014)** considered cumulative number of calls and saw a non-significant increasing risk with increasing exposure (Table 5). **Hardell et al. (2015)** used age and saw no pattern (Table 5).

Elliott et al. (2010) compared distance to power station, total power and modeled power to evaluate the contributions of mobile phone towers on the rates of brain and central nervous system tumors in young adults and basically saw no relationship. **Li et al. (2012)** did something similar but calculated exposure for an entire township instead of individuals. They saw slightly increased ORs for different types of divisions of the data and an increase in the risk of brain tumors of 1.09 (0.95-1.25) per standard deviation of their exposure density measure.

Aydin et al. (2013) looked at total cumulative years of use of a mobile phone by self-reporting and operator recorded cumulative years of use and saw marginal increases in risk with increasing exposure (p=0.14 and p=0.15 respectively, (Table 8)). When they also looked at cumulative hours of use for the self-reported and operator-recorded data, they saw no relationship although all ORs were greater than 1.

Table 9: Meta-Regression Exposure Values for Tables 11 and 12

Author (year)	Exposures (times 100 hrs)
Inskip et al. (2001)	0.065, 0.57, 5.00
Interphone (2010)	0.025, 0.09, 0.22, 0.46, 0.88, 1.575, 2.80, 5.475, 11.875, 82
Coureau et al. (2014)	0.215, 0.775, 2.255, 6.27, 44.8
Hardell et al. (2015)	0.615, 3.17, 9.99, 74.3
Yoon et al. (2015)	1.50, 6.00, 45

Table 10: Meta-Regression Analysis with Sensitivity Analysis of ORs for Five Case-Control Studies using Cumulative Hours of Use as the Exposure Metric and the Original Referent Groups

Meta Regression Studies[a,b]	Coefficient	P>|Z|	95% Confidence Interval		I^2	pQ
All	1.007	0.004	1.002	1.012	68.18	<0.001
drop Inskip et al. (2001)	1.007	0.004	1.002	1.012	71.34	<0.001
drop Interphone (2010)	1.011	<0.001	1.005	1.017	54.36	0.006
drop Coureau et al. (2014)	1.006	0.02	1.001	1.011	71.65	<0.001
drop Hardell et al. (2015)	1.004	0.184	0.998	1.010	61.27	0.001
drop Yoon et al. (2015)	1.008	0.001	1.003	1.013	69.85	<0.001
a – studies included in the analysis are Inskip et al. (2001), Interphone (2010), Coureau et al. (2014), Hardell et al. (2015), Yoon et al. (2015); b - Interphone Study uses <1 year duration of use as the referent group						

Table 11: Meta-Regression Analysis[a] with Sensitivity Analysis of ORs for Five Case-Control Studies using Cumulative Hours of Use as the Exposure Metric and the Alternative Referent Group for the Interphone Study

Meta Regression Studies[a,b]	Coefficient	P>|Z|	95% Confidence Interval		I^2	pQ
All	1.010	<0.001	1.006	1.014	33.95	0.054
drop Inskip et al. (2001)	1.010	<0.001	1.006	1.014	38.66	0.037
drop Interphone (2010)	1.011	<0.001	1.005	1.017	54.36	0.006
drop Coureau et al. (2014)	1.009	<0.001	1.005	1.013	35.34	0.065
drop Hardell et al. (2015)	1.008	0.003	1.003	1.013	0.49	0.451
drop Yoon et al. (2015)	1.011	<0.001	1.007	1.014	27.65	0.118

a – studies included in the analysis are Inskip et al. (2001), Interphone (2010), Coureau et al. (2014), Hardell et al. (2015), Yoon et al. (2015); b - Interphone Study uses greater than 0 and <5 hours cumulative use as the referent group

4.1.3.3 Strength of the Association

The strength of the association is tied to the magnitude of the response and the statistical significance of that response. For all of these studies, the actual magnitude of the RRs seen in the studies are small, in many cases falling below 1. It is clear from Figure 2, that the longer the duration, the larger the mRR and the more statistical significance to the risk. It is also clear from Figure 2 that the actual analysis used from the **Interphone study (2010)** can make a difference in the magnitude of the response. This is a strong set of findings.

In addition, laterality matters for addressing the strength of the association. Laterality seems to become more pronounced with a longer duration of exposure or greater cumulative hours of use. For ≥10 years of usage, the **Interphone study (2010)** has an ipsilateral RR of 1.21 (0.82-1.80) and a contralateral RR of 0.70 (0.42-1.15) whereas **Hardell et al. (2015)** saw an ipsilateral mRR of 2.24 (1.61-3.11) (pooling all categories above 10) and contralateral of 1.52 (0.99-2.34). Combining these by meta-analysis yields an mRR of 1.66 (0.91-3.04) for ipsilateral and 1.04 (0.49-2.23) for contralateral with significant heterogeneity (not shown). For cumulative duration of use in the highest category, the **Interphone study (2010)** has ipsilateral 1.96 (1.22-3.15) and contralateral 1.25 (0.64-2.43), **Coureau et al. (2014)** has ipsilateral 4.21 (0.70-25.42) and contralateral 1.61 (0.56-4.62), and **Yoon et al. (2015)** has ipsilateral 1.77 (0.32-1.84) and contralateral 0.63 (0.24-1.65). Combining these by meta-analysis yields an mRR of 1.99 (1.33-3.00) for ipsilateral and 1.11 (0.68-1.80) for contralateral with no heterogeneity (not shown). These results are surprisingly consistent and suggest a strong effect on laterality.

Finally, since the temporal lobe gets some of the highest fields when using a mobile phone, many researchers have looked at whether this location seems to associate with the use of mobile phones.

The Interphone study evaluated this for ≥10 years duration [1.36 (0.88-2.11)] and for ≥1640 hours cumulative use [1.87 (1.09-3.22)]. **Hardell et al. (2015)** did not address this issue for longer latency, but in one of their earlier studies, **Hardell et al. (2013)**, they found the following : 10-15 years latency 1.6 (0.7-4.1), 15-20 years 2.0 (0.8-5.2), 20-25 years 2.7 (1.02-7.3) and ≥25 years (4.8 (1.7-14). A meta-analysis of these numbers from **Hardell et al. (2013)** yields mRR 2.41 (1.49-3.89) (no heterogeneity) which, when combined with **Interphone (2010)** yields an mRR of 1.79 (1.02-3.14) (some heterogeneity, pQ=0.08). Regretfully, no other study looked at this issue for the highest exposure categories. However, 4 studies addressed this for the evaluation of ever versus never exposure and saw ORs of 0.86 (0.66-1.13) (Interphone), 3.94 (0.81-19.08) (Coureau), 4.30 (1.99-9.27) (Hardell) and 1.13 (0.86-1.48) (Frei.). The combined mRR for these 4 is 1.56 (0.88-2.77) with significant heterogeneity (not shown).

4.1.4 Ecological Epidemiology Studies of Malignant Brain Tumors and Gliomas

Ecological epidemiology studies attempt to look at trends of disease in a population and relate this to a particular exposure that changes over time or space in the population. The main difference between an ecological epidemiology study and the studies discussed up to this point (case-control and cohort studies) is that the unit of observation is a population, not an individual. Thus, ecological studies do not ask the individuals about their exposures but instead infer that exposure based upon other information. All of the ecological studies regarding cellular telephone use are based upon the idea that cellular telephone use has been increasing over time and this would imply that glioma rates in a population will be increasing in time as well. To be able to do this type of analysis, one would need to know the statistics on the use of cell phones in this population; something that is seldom known and must be inferred from statistics on ownership of a cellular phone or from the control populations in the case-control studies or from the usage seen in the cohort studies.

Usage data from the cohort studies, if obtained in a timely manner, would be a good estimate of usage in the general population. Regretfully, the two cohort studies in adults obtained these data early on in the use of cellular telephones (1982-1995 in Denmark and 1999-2005 in the UK) and their usage has increased dramatically since that time. Thus, it is hard to extrapolate from the usage in these populations to usage today. In the case-control studies, one can make assumptions of how well the cases and controls represent the general population, but these assumptions generally cannot be tested and may be wrong.

It is also required to have accurate information on cancers in a population. This type of information is usually derived from routinely collected national or regional statistics from cancer registries. Cancer registries can be notoriously inaccurate in the actual diagnosis of the cancer, gaps in coverage of a region or time and other problems. Because of all of these problems, ecological epidemiology studies are often affected by confounding or ecological fallacy (this occurs when inferences about what is happening at the individual level are derived from correlations seen in groups or populations). For these reasons, ecological studies are considered very weak in identifying or excluding risk factors that might be important in a population.

The ecological studies relevant to this review can be broken down into three categories: ecological studies on brain tumors in general, ecological studies on specific types of malignant brain tumors, and ecological studies on acoustic neuromas. In this section, I will review ecological studies on brain tumors and gliomas.

Deltour et al. (2009) [129] investigated temporal trends in glioma incidence rates in Denmark, Finland, Norway and Sweden using data from the national cancer registries. These data are intended to cover the populations incidence for 100% of the Nordic population and there is no discussion about limitations of the data for gliomas. They restricted their analysis to the years 1974-2003. They did a change-point analysis and saw no statistically significant change in incidence rates from 1998-2003, when they claimed changes caused by cell phones would be visible. They concluded any increase in gliomas caused by cell phones, if it exists, is not observable in this population. This is an extension of an earlier paper [130].

Inskip et al. (2010) [131] examined temporal trends in brain cancer incidence rates in the United States using data from the Surveillance, Epidemiology, and End Results (SEER) Program. For this analysis, they used SEER data from 9 cancer-registries which cover about 10% of the US population, restricted their analysis to Caucasians, and covered the years 1992-2006. They only saw increases in the 20-29 year age group in females. They also looked at specific locations in the brain and saw increases in both males and females in frontal lobe tumors. They concluded these findings do not support the view that use of cellular telephones increase cancer risks.

de Vocht et al. (2011) [132] examined temporal trends in brain cancer incidence rates in England using data from the UK Office of National Statistics. These data should cover 100% of the UK population, but there are gaps maybe as high as 35%. They restricted their analysis to the years 1998-2007. They saw no increases in any age group. They also looked at specific locations in the brain and saw increases in both males and females in temporal lobe tumors and in men only, frontal lobe tumors. They concluded these findings do not indicate a pressing need to implement a precautionary principle to reduce RF exposures.

Ding and Wang (2011) [133] investigated temporal trends in brain and nervous tissue cancer incidence rates in Shanghai using data from the Shanghai Cancer Registry. These data should cover 100% of the Shanghai population; gaps were not discussed. They restricted their analysis to the years 1983-2007. They saw a doubling of brain cancer incidence in this period with no statistically significant changes in the increasing rate at any specific time. They concluded the study did not support an increase in brain and nervous system tumors due to RF exposures because the trend began before the widespread use of cellular phones.

Aydin et al. (2011) [109] compared hypothetical incidence trends generated from the ORs seen in their study of childhood brain tumors to incidence data on brain tumors in children and adolescents aged 5-19 years between 1990 and 2008 from the Swedish Cancer Registry. They concluded the patterns did not match and that this indicates that short-term mobile phone use does not cause an increase in brain cancers in children. **Soderqvist et al. (2011)** [112] had concerns regarding the interpretation of these findings and suggested there could still be an effect. **Aydin et al. (2012)** [134] responded, basically reiterating their original arguments.

Deltour et al. (2012) [135] investigated temporal trends in glioma incidence rates in Denmark, Finland, Norway and Sweden using data from the national cancer registries. These data are intended to cover the populations incidence for 100% of the Nordic population and there is no discussion about limitations of the data for gliomas. In this period, incidence rates have increased slightly in men and women, mostly in older populations. Using simulation studies, various relative risks and various induction periods, they simulated the results of a cohort study on the entire population of men aged 40-59 years over this period (with complete follow-up). They then looked to see if they had a significant RR change in that population and equated that to being able to see a change in the incidence rates in the data from the cancer registries. The probability of seeing the change ranged from 2.9 % to 100% depending on the underlying simulation parameters. They concluded that many increased or decreased risks reported in case-control studies are implausible, implying that biases and errors in the self-reported use of mobile phone have likely distorted the findings. This conclusion is at best speculative because the simulations do not actually match the incidence data they are looking at or the analyses they did with the data.

Little et al. (2012) [136] examined temporal trends in brain cancer incidence rates in the United States using data from the Surveillance, Epidemiology, and End Results (SEER) Program. For this analysis, they used SEER data from 12 cancer-registries (coverage of the US population is unknown). They restricted their analysis to non-Hispanic white people and the years 1992-2008. Using the findings from **Interphone (2010)** and **Hardell et al. (2011)**, they predicted what the tumor incidence rates in 2008 should have been by using 1992-1996 as a baseline rate and US subscription data to drive the temporal change. They concluded that the results from **Hardell et al. (2011)** are not consistent with the US SEER data but that the results from the Interphone (2010) study are.

Barchana et al. (2012) [137] examined temporal trends in brain cancer incidence in Israel using data from the Israel National Cancer Registry. These data should cover 100% of the Israeli population and is 95% complete for brain tumors. They restricted their analysis to the years 1989-2009. They focused on high-grade versus low-grade gliomas in males and females. They also examined changes in laterality. They found a decrease in low-grade gliomas over this period and an increase in high-grade gliomas. They also saw an increase in laterality towards more left-sided tumors. They concluded the decrease in low-grade gliomas correlated with the introduction of mobile phone technology in Israel.

Hsu et al. (2013) [138] examined temporal trends in malignant brain cancer incidence rates and death rates in Taiwan using data from the Taiwan National Cancer Registry. There was no discussion of the quality of this cancer registry. They restricted their analysis to the years 2000-2009. Their entire evaluation consisted of a side-by-side comparison in a histogram of deaths, incidence and cell phone usage. No statistical evaluations were performed. They concluded there was no detectable correlation between morbidity/mortality of malignant brain tumors and cell phone use in Taiwan.

Kim et al. (2015) [139] investigated temporal trends in primary brain cancer incidence rates in New Zealand using data from the New Zealand Cancer Registry. These data should cover 100% of the NZ population and there is some discussion about changes in histological classification that could produce a false-negative finding. They restricted their analysis to the years 1995-2010. In general, they saw a decrease in brain tumors over this period with a larger decrease in women than in men. They saw a significant increase in all brain tumors in females aged 30-49, with increases in glioma of the parietal and temporal lobe. This finding was not consistent over other age groups or with the rates in men. They saw increases in the 70+ years group in most categories, but attributed that to better diagnosis, but with no justification. They concluded there has been no increase in primary brain tumors over this period.

Sato et al. (2016) [140] investigated temporal trends in malignant neoplasms of the central nervous system incidence rates in Japan using nationwide estimates of cancer incidence developed by the regional cancer registries. These estimates are intended to cover the populations incidence for 100% of the Japanese population and there is some discussion about limitations of the estimates. They restricted their analysis to the years 1993-2010. They focused on men and women in their 20s and 30s and used data from a survey of cellular phone use to determine if these increases could be due to cellular phone use using the highest response category from the **Interphone (2010)** study as the expected change in risk ratio. In general, they saw an increase in brain tumors over this period with a larger increase in men than in women. They were able to show that the observed increases were greater than what would be predicted for only heavy users and the **Interphone (2010)** OR of 1.4. They then went on to show that using ORs of 6 for men and 12 for women in their 20s and 4 for men and 7 for women in their 30s came close to matching the data. They then concluded that increases in cancers by sex, age and period are inconsistent with sex, age and period usage of mobile phones and thus cannot be explained by the mobile phones.

Chapman et al. (2016) [141] examined temporal trends in brain cancer incidence rates in Australia using data from the Australian Institute of Health and Welfare. These data should cover 100% of the Australian population, but there is no discussion of the quality of the data. They restricted their analysis to the years 1982-2012. They suggested incidence has risen slightly in males and remained steady in females. They then used cellular phone usage data from Australia and created hypothetical curves for a RR of 1.5 for users and a 10-year lag and a second hypothetical curve with a RR of 2.5 for heavy users (defined as >896 hours of cumulative use and assumed for 19% of all users) and a 10-year lag. They concluded the hypothetical curves were significantly different from the observed curves. They cited **Dobes et al. (2011)** [142] as showing no rise in brain tumors in Australia, however, this study concluded there was a significant rise in glioblastoma in Australia from 2000-2008 at an annual rate of 2.5%.

de Vocht (2016) [143] examined temporal trends in brain cancer incidence counts (not standardized rates) in England using data from the UK Office of National Statistics. These data should cover 100% of the UK population, but there are gaps maybe as high as 35% and a 5-year lag in getting complete data. He restricted the analysis to the years 1985-2014. He obtained cellular phone subscription data from the ITU. He built a Bayesian counterfactual model of glioma, glioblastoma, parietal lobe tumors and temporal lobe tumors with covariates annual cancer incidence, population size, median age, cigarette smoking, urbanization rate and a factor to account for data quality in a specific period. The counterfactual model was compared to a model including cell phone subscription rates with several cut points to allow for lag times. He concluded that for glioma, glioblastoma and malignant tumors of the parietal lobe, cell phone usage did not differ from the counterfactual model. For malignant tumors of the temporal lobe, he found cell phone usage could be a causative factor for these tumors. There was a major error in the data used for this analysis and a correction was published [144]. The author claimed it had no impact on the findings although it changed the directions of the effects seen. **de Vocht (2019)** [145] repeated this analysis for glioblastoma in specific brain regions and for meningiomas and acoustic neuromas. Excess of the counterfactual were seen for glioblastomas in the frontal and temporal lobe, but were predominantly in the highest age groups. No excesses were seen for acoustic neuromas or meningiomas. He concluded cell phones are unlikely to be causative for these tumors.

Hardell and Carlberg (2017) [146] demonstrated that the rates of brain tumors of unknown type obtained from the Swedish Inpatient Register were increasing in the years from 1998-2015. In contrast, brain tumor diagnoses confirmed by cytology/histology increased in the Swedish Cancer Registry. Brain tumors diagnosed by MRI and CT are not always reported to the Swedish Cancer Registry. This suggests an under-reporting of brain cancers in the cancer registry and they suggest caution in using cancer registry data to understand any linkage between cellular phone usage and brain cancers. This was also suggested in an earlier evaluation by this group [147].

Phillips et al. (2018) [148] examined temporal trends in brain cancer incidence in England using data from the UK Office of National Statistics. These data should cover 100% of the UK population, but there are gaps maybe as high as 2% and a multi-year lag in getting complete data. They restricted their analysis to the years 1995-2015. They looked at a number of different forms of brain tumors and locations. They saw an increase in glioblastomas for 2011-2015 relative to 1995-1999 by age groups, with the largest increases in the higher age groups. The greatest increases were tumors in the frontal and temporal lobes. They suggest that widespread environmental or lifestyle factors may be responsible, but did not draw any conclusions regarding cellular phones.

Keinan-Boker et al. (2018) [149] examined temporal trends in brain cancer incidence in Israel using data from the Israel National Cancer Registry. These data should cover 100% of the Israeli population and is 95% complete for brain tumors. They restricted their analysis to the years 1990-2015. They focused on benign versus malignant tumors by age and sex. In general, they saw a mixed set of effects that changed over these categories. In conclusion, they found the results to be not consistent with the penetrance of cellular phones in Israel over this period.

Karipidis et al. (2018) [150] examined temporal trends in brain and central nervous system tumor incidence rates in Australia using data from the Australian Institute of Health and Welfare. These data should cover 100% of the Australian population, but there is no discussion of the quality of the data. They restricted their analysis to the years 1982-2013 and cases aged 20-59 years. There is no discussion of standardizing the rates. Percent of the population with mobile phone subscriptions was obtained from the Australian Communications and Media Authority. They used a very simple model to predict incidence rates from subscription data using regular users and heavy users (19%) and various lag times. They concluded that there was no evidence that mobile phone use correlated with any brain tumor histological type or subtype.

Nillson et al. (2019) [151] examined temporal trends in glioma incidence rates in Sweden using data from the Swedish Cancer Registry. These data should cover 100% of the Swedish population. They restricted their analysis to the years 1980-2012 because problems with the registry starting in 2013. They saw no increases in age-standardized incidence rates over time and a significant decrease in low-grade gliomas. They concluded these findings do not indicate any effect of RF exposures on gliomas incidence.

Natukka et al. (2019) [152] examined temporal trends in glioma incidence rates in Finland using data from the Finnish Cancer Registry. These data should cover 100% of the Finnish population. They restricted their analysis to the years 1990-2016 with cases reclassified from 1990 to 2006 to match modern classifications. The data for 2007-2016 could not be classified by sex or age grouping. They discussed several major limitations of their analyses including misclassification, limitations to the analysis and small sample sizes. They saw no increases in age-standardized incidence rates for gliomas over 1990-2006 but could not do this analysis beyond then. There were no major changes in tumor locations over time.

These studies use a variety of different cancer registries and a variety of different methods to evaluate the relationship between temporal changes in brain cancer incidence and the use of mobile phones. Most studies find the relationship between increasing mobile phone use and incidence of brain tumors are inconsistent. However, all of these studies suffer from a variety of problems that are common with ecological studies. In most studies, the surrogate for individual exposure is derived from subscription data and not from actual cellular phone use data. Even in cases where exposure is used (such as high cumulative use), the exposure is simply expressed as a simple percentage of the population. The choice of tumor to examine can have a major impact on the trend as can the statistical model used to examine the data (this is clearly exemplified by the studies using the same UK data and seeing very different results). In many cases, the tumor incidence rates are increasing, but there was insufficient statistical power to identify if the increase matches the increase in cellular phone usage and these were uniformly interpreted as showing no relationship. Finally, the cancer registries themselves have limitations and flaws that may also lead to ecological fallacies regarding their linkage to cellular phone usage.

4.1.5 Conclusions for Gliomas

The evidence on an association between cellular phone use and the risk of glioma in adults is quite strong. While there is considerable difference from study to study on ever versus never usage of cellular phones, 5 of the 6 meta-analyses in Figure 1 are positive and two are significantly positive. Once you consider latency, the meta-analyses in Figure 2 clearly demonstrate an increasing risk with increasing latency. The exposure response meta-regressions in Table 10 and Table 11 clearly indicate that risk is increasing with cumulative hours of exposure, especially in the highest exposure groups. There is a strong tendency toward gliomas appearing on the same side of the head as the phone is generally used and the temporal lobe is strongly suggested as a target. These findings do not appear to be due to chance. The cohort studies appear to show less of a risk than the case-control studies, but one study is likely to be severely impacted by differential exposure misclassification (Frei et al., 2007) and the other (Benson et al., 2012) is likely to have a milder differential exposure misclassification. The case-control studies are possibly impacted by recall bias although that issue has been examined in a number of different evaluations. Selection bias could have been an issue for the Interphone study, but their alternative analysis using different referent groups reduces that concern. Confounding is not an issue here. In conclusion, an association has been established between the use of cellular telephones and the risk of gliomas and chance, bias and confounding are unlikely to have driven this finding. The ecological studies are of insufficient strength and quality to fully negate the findings from the observational studies.

The data in children is insufficient to draw any conclusions.

[illegible] Acoustic Neuromas

[illegible] Studies in Adults

[illegible]

Hardell et al. (1999) [85] did an analysis of acoustic neuromas in their study and saw an OR of 0.78 (0.14-4.20) based on 13 cases. No other information is provided. ([illegible])

Inskip et al. (2001) [44] saw no increases for acoustic neuromas in their study described on page [illegible]. ([illegible])

Muscat et al. (2002) [153] conducted a case-control study of acoustic neuromas from two hospitals in New York city as part of their larger study on brain tumors described on [illegible]. Cases were 18 years of age or older with histologically confirmed acoustic neuromas from 1997 to 1999. There were 90 cases (response rate appears to be 100%) and 86 hospital-based controls matched on age (5-years), sex, race and hospital. Interviewer-based structured questionnaires were used. Regular use was determined by simply asking the patient if they were a regular user. No OR was provided on regular users, but ORs were calculated for years of use, hours/month of use, and total hours. No obvious pattern existed for any of these categories. Ipsilateral use was evaluated using the **Inskip et al. (2001)** [44] method with an OR of 0.9, p=0.07. The main weakness in this study is the potential for recall bias, small sample size, and the short latency. ([illegible])

Warren et al. (2003) [154] conducted a case-control study of intratemporal facial nerve tumors (age not given) in a tertiary care medical center from July 1, 1995 to July 1, 2000 in the United States. As matched controls, and to serve as an alternative case group, they chose 51 acoustic neuroma patients from the same facility. They also had rhinosinusitis controls, dysphonia or gastroesophageal reflux controls and two non-tumor control groups. Matching was based on age (+/- 6 years), sex and race. Cellular telephone usage was assessed via a detailed questionnaire. The study had 51 cases of acoustic neuroma matched with 141 rhinosinusitis, dysphonia or gastroesophageal reflux controls (participation rates were not provided). Ever use of a handheld cellular phone had an OR of 1.2 (0.6-2.2) and use of a handheld cellular phone for more than 1 call per week had an OR of 1.0 (0.4-2.2). They assessed use of tote phones and car phones as well. This is a very small study with limited details. ([illegible])

Baldi et al. (2011) [89] saw no increases for acoustic neuromas in their study. ([illegible])

The Interphone Study Group (2011) [67] also did a case-control study on acoustic neuromas using the same protocol as their brain cancer study [48] shown on [illegible]. As for brain tumors, there were a number of publications from individual countries and/or sub-groups of countries for acoustic neuromas [50, 53, 54, 57, 58, 60, 66, 155, 156]. The odds ratio (OR) of acoustic neuroma with ever having been a regular mobile phone user was 0.85 (95% confidence interval 0.69–1.04). The OR for ≥10 years after first regular mobile phone use was 0.76 (0.52–1.11). There was no trend of increasing ORs with increasing cumulative call time or cumulative number of calls, with the lowest OR (0.48 (0.30–0.78)) observed in the 9th decile of cumulative call time. In the 10th decile (≥1640 h) of cumulative call time, the OR was 1.32 (0.88–1.97); there were, however, implausible values of reported use in those with ≥1640 h of accumulated mobile phone use. With censoring at 5 years before the reference date the OR for ≥10 years after first regular mobile phone use was 0.83 (0.58–1.19) and for ≥1640 h of cumulative call time it was 2.79 (1.51–5.16), but again with no trend in the lower nine deciles and with the lowest OR in the 9th decile. In general, ORs were not greater in subjects who reported usual phone use on the same side of the head as their tumor than in those who reported it on the opposite side, but it was greater in those in the 10th decile of cumulative hours of use. [partially copied from abstract] (Table 12, Table 13, Table 14, Table 16, Table 17)

Han et al. (2012) [157] conducted a case-control study on patients with acoustic neuromas who underwent surgery from 1997 to 2007 at the University of Pittsburgh medical center. The cases were sent questionnaires in 2009-2010 and then interviewed over the phone. Controls were from the outpatient clinic for degenerative spinal disorders at the same medical center, but during the years of 2009-2010. There were eventually 343 (59% response) cases and 343 (response rate not given) controls matched on sex and age (+/- five years). If age-matching was done based on the time of diagnosis for the case or at the time of the questionnaire administration, there should be no problem, but if age-matching was done as diagnosis for the patient matched to current age of the control, this would be a problem for the analysis of cell phone usage. Their main interest was in the relationship between dental x-rays and AN, but they asked about cell-phone usage as a side issue in order to adjust their main analyses on x-rays for cell phone usage. It is not clear exactly how exposure to cellular phones was assessed. If it was done right, regular usage was assessed at the time of the AN patient's diagnosis and the matching control was assessed the same way. The same would need to be true for the duration of use. Any other way in which exposure was assessed would render the interpretation of this study difficult. The questionnaire was not available to address these questions and the write-up does not explicitly make this clear. Assuming the case matching was done correctly and exposure was done correctly, they saw no increased OR [0.95 (0.58-1.58)] for regular use (defined as 1 call per week for 6 months or more) or for use ≤10 years [0.79 (0.45-1.37)] and saw an increased OR for ≥10 years of use [1.29 (0.69-1.63)]. Regular use of a cellular phone was a significant confounder (p=0.006) in their analysis of X-rays and AN. (Table 12, Table 13)

As for malignant brain tumors, **Hardell and colleagues** have published a number of studies on acoustic neuromas and cell phone usage [82, 158-160]. **Hardell et al. (2013)** [82] used data collected at the same time as their pooled case-control study on malignant brain tumors [88], described on page 16, to do a pooled case-control study on acoustic neuromas and cellular phone usage. ORs tended to increase with years of latency with the highest ORs in the longest latency group (>20 years), ORs tended to increase with cumulative use with the largest OR in the highest exposure quartile (>1486 hours cumulative use), ipsilateral ORs were larger than contralateral ORs and changes in tumor volume seemed to be associated with cumulative use. (Table 12, Table 13, Table 14, Table 16, Table 17)

Corona et al. (2012) [161] identified cases of unilateral AN in people ≥18 years of age residing in the municipalities of Salvador and Feira de Santana in Brazil from 2000 to 2010. For each case, they selected 3 controls from the same outpatient clinics as the cases and had visited the doctor "immediately after each case visit". They identified 85 AN patients and 181 controls of which 44 (51.8%) of the cases participated and 104 (57.4%) of the controls participated. There was no description of whether cases and controls were matched on any factor other than clinic. Exposure and demographic information was obtained by interview-administered questionnaire for both cases and controls. For regular use of a mobile phone (defined as one call per week for 6 months), the OR was 1.38 (0.61-3.14). For <6 years of phone use, the OR was 1.14 (0.42-3.08) and for ≥6 years it was 1.81 (0.73-4.47). They also looked at minutes of use per day (≤10, 11-30, >30) and saw increased ORs (1.49 [0.59-3.77], 1.77 [0.62-5.06], 1.15 [0.33-4.08]). Ipsilateral use showed an OR of 1.40 (0.65-3.04) and contralateral use showed an OR of 0.57 (0.23-1.43). (Table 12, Table 13, Table 15, Table 17)

Pettersson et al. (2014) [156] identified incident cases of acoustic neuroma (n = 542) between 20 and 69 years of age at diagnosis from September 2002 to August 2007 in Sweden. Controls (n=1095) were randomly selected from the Swedish population register, matched on age, sex and health-care region. Of these, 451 (83%) cases and 710 (65%) controls participated. The controls were assigned a reference date that corresponded to the date of diagnosis of their matched case. Self-reported exposure information was collected through postal questionnaires, sent to cases and their matched controls simultaneously, starting in October 2007. The referent group was regular users defined as having made or received on average at least one call per week over the last 6 months. Analyses were conducted on all cases and controls and then on cases and their matched controls for which the case was histologically confirmed (47% of cases). The OR for regular use is 1.18 (0.88-1.59). For duration of use, they saw an elevated OR for 5-9 years [1.40 (0.98-2.00)], but not for < 5 years [1.04 (0.72-1.52)] or ≥10 years [1.11 (0.76-1.61)]. Cumulative hours of use saw an exposure-response pattern with the highest OR [1.46 (0.98-2.17)] in the highest exposure group. Cumulative calls saw a similar pattern. When ORs are evaluated for any analog phone usage, the ORs generally increased and the pattern for time since first regular use began is decreasing with years. For digital phones, the pattern is the same as for all phones, with slightly larger ORs. The ORs for histologically-confirmed cases only generally has smaller ORs. ORs for ipsilateral use were generally lower than for contralateral use and near or below 1.0. Over half of the cases who were regular users noted they changed their preferred side of mobile use, mostly due to hearing loss. They attempted to evaluate this issue, but their definition of ipsilateral (having held the mobile phone on the tumor side or on both sides during any period before the reference date) would make it virtually impossible to see an increase in ipsilateral use [NOTE: most studies ask which is the usual hand for holding the mobile phone]. Contralateral was also defined using both sides (or opposite side). This problem is best seen when they looked at laterality over time; at the time of filling in the questionnaire, ipsilateral was 0.31 (0.18-0.53) and contralateral was 2.09 (1.45-3.00) whereas at five years before the reference date, ipsilateral was 0.97 (0.66-1.42) and contralateral was 1.33 (0.89-2.27). They evaluated the potential for recall bias for start year and found no systematic errors that were different between cases and controls [162]. (Table 12, Table 13, Table 14, Table 16, Table 17)

4.2.1.2 Case-Case Studies

Sato et al. (2011) [163] conducted a case-case study of mobile phone use and acoustic neuromas in Japan. Inclusion criteria were all verified cases occurring between January, 2000 and December, 2006 in 22 hospitals recruited to be in the study (32.4% of those asked). Phone usage and other information were obtained by written questionnaire sent to the patient. A total of 1589 cases met the inclusion criteria of which 787 (49.5%) eventually were included in the analysis. Reference dates were set at 1 year and 5 years before diagnosis. The case-case analysis is based upon three assumptions: (1) there was no risk from mobile phones to the contralateral side; (2) risk to the ipsilateral side was the same for left- and right-sided users; and (3) for non-users, incidence of left- and right-sided tumors was the same. Hence, contralateral cases served as controls. Weighted average number of calls per day, weighted average duration of one call and weighted average daily call duration at 5 years prior to diagnosis were all significantly increased (0.043, 0.017, and 0.004 respectively). In addition, patients with an age at diagnosis of <40 years (41 patients) had a significantly increased OR (1.72 [1.08-3.10]). Heavy users (>20 minutes per day) had increased ORs regardless of whether that heavy use was for 1 (2.7 [1.2-7.9]) or 5 (3.1 [1.5-7.4]) years or both (5.0 [1.4-24.8]) or only 5 years (1.9 [0.9-5.8]) before diagnosis, but not for only the period 1 year before diagnosis (0.9 [0.6-2.6]). Tumor sizes tended to be smaller with ipsilateral use compared to contralateral use. The main weaknesses of this study are the potential for recall bias due to the mail-in questionnaire and the low response rate. (Table 17)

4.2.1.3 Cohort Studies

Schuz et al. (2011) [99] used the same cohort as **Frei et al. (2011)** [96] to evaluate the incidence of acoustical neuromas in humans associated with mobile telephone use (description of the cohort on page 19). The cohort was updated to include follow-up to 2006. The results pertain only to people who used phones for greater than 11 years (because of the 1995 cut-off for knowledge of who had a cellular phone subscription) and the referent group is all non-users and people who got phones after 1995. They saw no association (men 0.88, 0.52-1.48, no observed tumors in female users). They also saw no impact of long-term mobile phone use on the size of the tumors. This study has the same limitations of other evaluations with this cohort. There are earlier publications on this cohort [94, 95]. (Table 12)

Benson et al. (2013) [102] also studied acoustic neuromas in their cohort study described on page 19. Relative risks (RRs) for phone use were ever/never 1.44 (0.91-2.28), daily use 1.44 (0.91-2.28)), <5 years 1.0 (0.54-1.82), 5-9 years 1.80 (1.08-3.03) and 10+ years of use 2.46 (1.07-5.64) (all adjusted for socioeconomic status, region, age (in 3-year groupings), height, BMI, alcohol intake, exercise and hormone therapy). In a letter responding to a letter by **de Vocht (2014)** [105], **Benson et al. (2014)** [106] updated their follow-up to 2011 but did not update cellular phone usage (still relying on the 1999-2005 response) and saw OR for acoustic neuroma for ever/never users of 1.19 (0.81-1.75). Note that with 7 years average follow-up, they saw 96 acoustic neuromas or 13.7/year but adding 2010 and 2011 increased the acoustic neuromas by 15 per year. The same limitations mentioned on page 19 also apply here. (Table 12, Table 13)

4.2.2 Studies in Children

I could not identify any studies on acoustic neuromas in children and exposure to RF or cellular telephones.

4.2.3 Discussion

As for gliomas, I will focus on three areas of interest from the epidemiology studies of acoustic neuromas (AN); consistency of the association, the existence of an exposure-response relationship, and the strength of the association.

4.2.3.1 Consistency of the Association

The studies to be considered are listed in Table 12 and **Muscat et al. (2002)** in Table 13. All of these studies did a reasonable job of addressing confounders in their analyses and so this problem will not be discussed further. First, we should consider timing of the study. As mentioned earlier, for studies in the 1990s, we are looking at a rare exposure and trying to associate it with a rare disease (AN) and probably with very little time from the beginning of exposure to disease onset. Thus, it is unlikely that **Hardell et al. (1999)** [85], **Inskip et al. (2001)** [44], **Muscat et al. (2002)** [153], **Warren et al. (2003)** [154], and **Baldi et al. (2011)** [89] would show much of an association. And that is basically the case, with these studies producing ORs of approximately 1.0. The later studies are more likely to show an effect if one exists than these early studies and these should be given greater weight.

The size of a study will also matter since studies with greater numbers of cases and controls (especially exposed cases) will generally have smaller confidence bounds and have a greater chance of seeing an effect if one exists. Thus, the studies by **Hardell et al. (1999)** [85], **Inskip et al. (2001)** [44], **Muscat et al. (2002)** [153], **Warren et al. (2003)** [154], **Baldi et al. (2011)** [89], **Corona et al. (2012)** [161], **Benson et al. (2013)** [102] and **Schuz et al. (2011)** [94] will carry less weight in an overall evaluation.

There are also studies where the referent group was “never used a mobile phone” versus studies where the referent group was “not a regular user of mobile phones” defined by different measures. Less weight should be given to studies with comparisons to “never used” simply because the “ever used” group could include people who used a phone only a few times.

Given these caveats, there are five case-control studies that should carry the greatest weight: **Interphone (2010)** [67], **Hardell et al. (2013)** [160], **Han et al. (2012)** [157], **Corona et al. (2012)** [161], and **Pettersson et al. (2014)** [162]. Three of these 4 studies have ORs greater that 1.0 for regular usage of a cellular phone with 1 (**Hardell et al. (2013)** [160]) being significantly >1 [1.6 (1.2-2.2)].

The largest study, **Interphone (2010)** [67] has an OR for regular use of 0.85 (0.69-1.04). The difference in the response rate for cases (82%) versus controls (53%) could lead to problems with selection bias as was suggested for the brain tumor data from the Interphone study [74]. This study demonstrated no increases in OR with duration of use, even with a 5-year latency. (Table 12, Table 13)

The next largest study, and **Pettersson et al. (2014)** [162], had approximately half the number of exposed cases as **Interphone (2010)** [67] and showed an OR for regular use of

1.18 (0.88-1.59). They saw an increased OR for 5-9 years duration of use [1.39 (0.97-1.97)] which dropped for ≥10 years durations [1.09 (0.75-1.59)]. They had a non-responder questionnaire which was answered by 93 controls and 7 cases. Of the 93 control non-responders, 62 (67%) were regular mobile phone users compared to 442 (69%) out of 643 responding controls. There were only 7 non-responder cases who replied to the questionnaire and 4 were regular phone users. Thus, even though there are a larger number of non-responders in controls, there is no obvious suggestion of selection bias. (Table 12, Table 13)

Hardell et al. (2013) [160] was the next largest study with roughly 1/3 of the number of exposed cases as **Interphone (2010)** [67]. They saw an OR for regular use of 1.6 (1.2-2.2) and an increasing risk with increasing duration of use. In addition, all of the 5-year groupings of duration of use were greater than 1 and all usage longer than 5-years was significantly greater than 1 (Table 13). Only living cases were included. Their response rate was high enough that participation bias is unlikely to have lowered the OR values. Recall bias could have increased the ORs. In one of the original case-control studies [117] used in their pooled analysis, they evaluated this issue and saw little indication of recall bias with regard to malignant brain tumors (no information on AN). (Table 12, Table 13)

Han et al. (2012) [157] also was about 1/3 of the number of exposed cases as **Interphone (2010)** [67]. They saw an OR for regular use of 0.95 (0.58-1.58) and an increasing risk with increasing duration. It is impossible to judge the potential for selection bias since they gave no indication of the response rates for controls. In addition, it is also impossible to judge the quality of the exposure metrics since there was insufficient detail to understand how they related controls to cases in obtaining this information. (Table 12, Table 13)

Corona et al. (2012) [161] had 34 exposed cases or about 20x smaller than **Interphone (2010)** [67]. They saw increased ORs (non-significant) for all categories of usage. The response rates for cases and controls were moderate but not remarkably different suggesting no problem with selection bias although there was no follow-up with non-respondents. It is not possible to judge recall bias in this small study. (Table 12, Table 13)

Sato et al. (2014) [163] is the next largest study; but being a case-case study, it is more relevant to the issue of laterality and will be discussed later.

Schuz et al. (2011) [99], with only 15 exposed cases, is a cohort study with limitations due to potential differential exposure misclassification (discussed earlier). They saw an OR for subscriptions from 11 years prior to reference date of 0.86 (0.52-1.46). (Table 12)

Benson et al. (2013) [102], with only 8 cases that are daily users, saw an OR of 1.37 (0.61-3.07). They had 67 ever users in the cases and these had an OR of 1.44 (0.91-2.28). Using never use as the reference category, they looked at duration of use and saw clearly increasing ORs with increasing duration. This study may also have problems with exposure misclassification (discussed earlier). (Table 12, Table 13)

Roosli et al. (2019) [118] also did a meta-analysis of AN and cellular phones. They give mRRs for the analyses of studies showing ORs for ≥10 years exposure. For the case-control studies, they get an mRR of 1.29 (0.74-2.23). For the Cohort studies, they show an mRR of 0.98 (0.65, 1.48) and for all studies combined they get 1.19 (0.80-1.79). Entering their numbers into Stata (v 16.2 for MAC), I can reproduce their findings. They also did a meta-analysis of ever versus never use for all 9 case-control studies (1.05 [0.84-1.32]) and the cohort studies (0.93 [0.57-1.50]) with a combined mRR of 1.02 (0.84-1.24). They show a number for regular use from **Muscat et al. (2002)** [153] which is not in the paper and appears to be the unadjusted crude OR. They give no reason for using **Shuz et al. (2006)** [94] instead of **Schuz et al. (2011)** [99] for this analysis although they used **Frei et al. (2011)** [96] for their analysis of gliomas. I am also unable to match the number they use for **Benson et al. (2013)** [102] which they list as 1.19 (0.81-1.75) but the paper lists as 1.37 (0.61-3.07). They also conducted a cumulative meta-analysis of the studies with ≥10 years of use. They also did several other analyses of ever versus never use with no appreciable changes in the results. One problem with these meta-analyses is that they give very little weight to the largest studies. They did not consider laterality or tumor location in the brain.

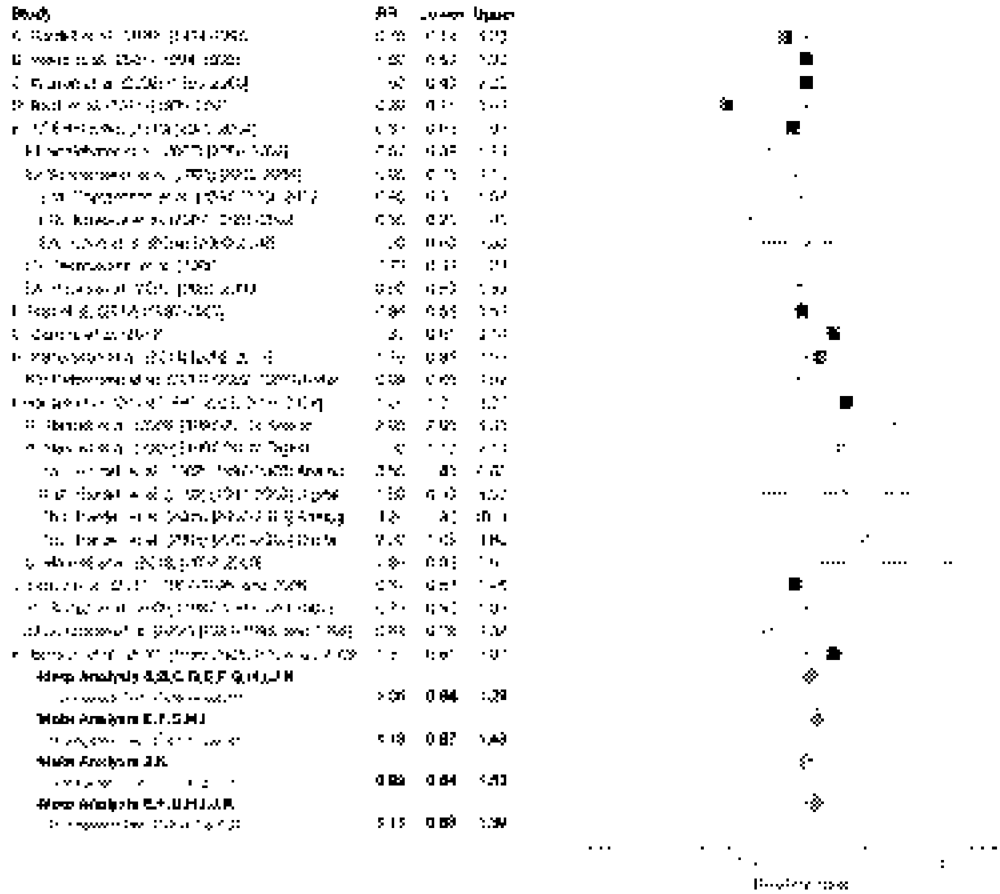
The remaining meta-analyses are older and use fewer and fewer of the individual studies.

To provide a better evaluation of the results, Figure 3 is a forest plot of all of the ORs from individual publications that evaluated regular use versus minimal or never use or ever use versus never use (if both were given in a study, regular use is shown). The column labeled "Study" provides the reference to the publication and the years in which cases and controls were collected for case control studies and the years when phone use information was collected for cohort studies and the year in which follow-up ended. Some studies are pooled evaluations of multiple other studies, so the other studies are indented. The column labeled "RR" is the risk ratio (OR, RR or mRR) from the study, "Lower" and "Upper" are the lower and upper bound on a 95% confidence interval around the RR. The graphic on the right simply plots the RR as a square or diamond with the "whiskers" (blue line running through the box) showing the width of the 95% confidence interval. The vertical line passing through 1 represents no effect. If the box and both whiskers are to the right of this line (greater than 1) and not touching it, this finding is statistically significant with a positive effect; if they fall completely to the left of the vertical line (below 1), then the risk is significantly reduced. The blue boxes that are filled in are major studies, the blue boxes that are white in the middle are the sub-studies and the red diamonds are all meta-analyses.

The graphic in Figure 3 is very useful for examining these types of data in a single view. Looking just at the filled in blue blocks (Studies A,B,C,D,E,F,G,H,I,J,K), 5 studies have their ORs below 1, two are equal to 1 and four are above 1. One study (I) shows a significant increase in risk. The first meta-analysis (Meta Analysis A,B,C,D,E,F,G,H,I,J,K) combines the information from all of the studies to produce an mRR of 1.06 (0.88-1.29) suggesting that all of the positives and negatives balance out to a small, non-significant increased risk. However, as mentioned earlier, the newer, larger studies represent longer exposures, so I have also done meta-analyses on the five case-control studies that collected cases after 2002 (E,F,G,H,I) and the two cohort studies (J,K). Combining the five case-control studies (Meta Analysis E,F,G,H,I) results in a mRR of 1.13 (0.87-1.48), a slight increase in risk from the use of a mobile phone, but heterogenous across studies. The combined cohort studies yield a mRR of 0.99 (0.64-1.53) suggesting no risk, and no heterogeneity (p=0.35). Combining the 5 case-control studies and the 2 cohort studies (Meta Analysis E,F,G,H,I,J,K) yields an mRR of 1.11 (0.88-1.39) again suggesting marginal risk but with significant heterogeneity (p=0.04).

Figure 4 is a forest plot of all of the ORs from individual publications that reported on duration of use ≥5 years or more. There are 8 studies; 5 of these studies show groupings of 1-4 years, 5-9 years and ≥10 years, one study with groupings of <6 years, and ≥6 years, one study with ≥5 years and one study with <10 years and >10 years. For the study by **Hardell et** al. (2013) [160], groupings of 10-14, 15-19 and ≥20 years were combined by meta-analysis to get a single mRR for ≥10 years. There are 2 groups of meta-analyses each with three separate meta-analyses for 1-4 years, 5-9 years and ≥10 years (combined with only ≥10 years for **Han et al. (2012)** [157] and <6 years for **Corona et al. (2012)** [161]). The first group of 3 meta-analyses combines the case-control studies and the second group of 3 meta-analyses adds in the cohort studies. In order to accommodate the study by **Inskip et al. (2001) [44]** with only a ≥5 year grouping and the study by **Corona et al. (2012)** [161] with ≥6 years, all studies with 5-9 and ≥10 years were combined in the last 2 meta-analyses to yield mRRs for ≥5-6 years for the case-control studies and all of the studies. The mRRs for <5 years are all near 1. The mRRs for 5-10 years are all elevated and close to statistical significance. The mRRs for ≥10 years are elevated, but less than for 5-10 years. Finally, both of the mRRs for ≥5 years are significantly elevated.

The studies in adults of an association between cellular phone use and acoustic neuroma are consistent enough to conclude an association exists.



[illegible]: Forest plot and meta-analyses of regular use or ever use of cellular telephones and the risk of acoustic neuroma [studies with a solid blue square either single studies that stand alone or pooled studies that encompass numerous single studies; open squares are individual studies or smaller pooled studies; red diamonds are meta analyses][a]

[a] - The column labeled “Study” provides the reference to the publication and the years in which cases and controls were collected for case control studies and the years when phone use information were collected for cohort studies and the year in which follow-up ended. Some studies are pooled evaluations of multiple other studies, so the other studies are indented. The column labeled “RR” is the risk ratio (OR, RR or mRR) from the study, “Lower” and “Upper” are the lower and upper bound on a 95% confidence interval around the RR. The graphic on the right simply plots the RR as a square or diamond with the “whiskers” (blue line running through the box) showing the width of the 95% confidence interval. The vertical line passing through 1 represents no effect. If the box and both whiskers are to the right of this line (greater than 1) and not touching it, this finding is statistically significant with a positive effect; if they fall completely to the left of the vertical line (below 1), then the risk is significantly reduced. The blue boxes that are filled in are major studies, the blue boxes that are white in the middle are the sub-studies and the red diamonds are all meta-analyses. “Homogeneity Test” provides the I^2 statistic and the p-value for the Q-test.

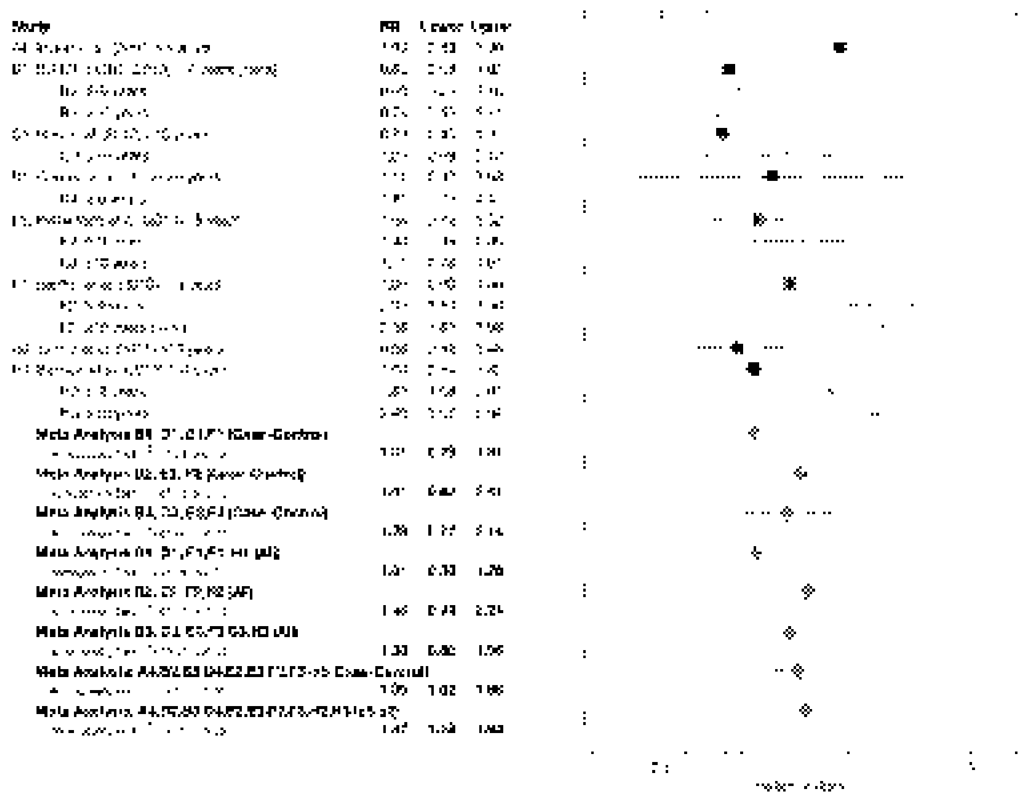


Figure 4: Forest plot and meta-analyses of duration of use of cellular telephones and the risk of acoustic neuroma [studies with a solid blue square are stand alone; red diamonds are meta-analyses, the columns and the figure are as in Figure 1]

[illegible]

As for gliomas, the best measure for exposure-response relationships is the cumulative hours of use of a cellular telephone since it includes both the frequency of use and the duration of use. While duration of use is also a form of exposure-response, it is more likely that, similar to ionizing radiation, RF is likely to have an association between total accumulated exposure and the risk of AN if a relationship exists. Table [illegible] provides the results for all of the epidemiology studies with estimates of the cumulative use of cellular phones.

Inskip et al. (2001) [44] shows consistent exposure-response and has two of the three ORs above 1. **Muscat et** al. **(2002)** [153] shows no increased risk. **Interphone (2010)** [67] basically shows flat exposure-response for the entire study until the largest exposure category, that is elevated in risk with an OR of 1.32 (0.88-1.97). The same pattern holds with a 5-years lag although the highest exposure group is now statistically significant with an OR of 2.79 (1.51-5.16). **Pettersson et al. (2014)** [162] saw a clearly increasing exposure-response pattern with ORs above 1 in all exposure categories and becoming almost significant in the highest exposure category [1.46 (0.98-2.17)]. **Hardell et al. (2013)** [160] saw a pattern of increasing risk with increasing exposure with 3 of their 4 categories statistically significant. They also did a regression resulting an OR of 1.009 (1.001-1.017) per hundred cumulative hours

It is not possible from the published results to find categories of exposure that match across the various studies in order to do a simple meta-analysis by category. However, it is possible to do a meta-regression where the exposure categories are turned into a single exposure and the meta-regression tests to see if the slope of the data from the various studies is increasing with exposure. As for glioma (Section 1.3.2, page 41), I set the exposure for each category equal to the center of the interval defined for the category and or the last category, which is generally expressed as ≥ some number of hours, I used the difference between the middle of the second largest category and the lower bound of that category and added it to the upper end of the second highest category to get the exposure for the highest category. The exposures for all of the categories of the studies entering into the meta-regression are shown in Table 18. As a check, a meta-regression was performed of just the **Hardell et al. (2013)** [160] study; the mRR is 1.015 (1.000-1.030) per 100 hours with p=0.05 compared to 1.009 (1.001-1.016) per 100 hours seen by **Hardell et al. (2013)** [160] using the original data.

Table 19 provides the results of the meta-regression for the 5 case-control studies with duration of exposure where all of the ORs are a comparison against non-regular users. There is a significant association between exposure and risk with a mRR of 1.007 (1.001-1.013, p=0.017). This is almost identical to what was seen by Hardell et al. (2015) [1.009 (1.001-1.016)]. The test of heterogeneity is significant (pQ<0.001) and an I^2 of 57.31. Removing **Interphone (2010)** [67] doubles the mRR to 1.014 (1.066-1.024) and reduces heterogeneity. Removing **Pettersson et al. (2014)** [162] results in no change in the mRR and slightly wider confidence intervals that barely include 1. Removing **Hardell et al. (2013)** [160] cuts the mRR in half and leads to a non-significant risk (1.003 [0.998-1.009; p=0.250) and reduces heterogeneity. The alternative high dose yielded the same pattern but higher mRRs per 100 hours, larger confidences bounds, less statistical significance and less heterogeneity (not shown). (Table 19)

<u>There were other measures</u> of exposure used in the various studies that are worth mentioning. **Inskip et al. (2001)** [44] used average minutes/day and saw no exposure-response relationship (Table 15). **Corona et al. (2012)** [161] also used average minutes/day and saw an increasing exposure response in the first 2 groupings and a lower OR in the highest grouping, all increased but with lower confidence bounds below 1 (Table 15). **Muscat et al. (2002)** [153] used hours/month and saw no pattern (Table 15). **Inskip et al. (2001)** [44] also considered the year that cellular telephone use began and again saw no exposure-response (Table 16). **Interphone (2010)** [67] considered cumulative use by years of duration of use (1-4 years, 5-9 years and ≥10 years). In 1-4 years and 5-9 years duration categories, they saw flat exposure-response. The highest cumulative use, ≥1640 hours, in the highest duration of use category, ≥10 years, was significantly increase (1.93 [1.10-3.38]) (Table 16). **Pettersson et al. (2014)** [162] considered cumulative number of calls and saw a flat exposure-response with all ORs above 1.0 (Table 16).

[illegible]: Meta-Regression Exposure Values for Table 19

Author (year)	Exposures (times 100 hrs)
Inskip et al. (2001)	0.065, 0.57, 1.435
Muscat et al. (2002)	0.30, 3 (0.90[a])
Interphone (2010)	0.025, 0.09, 0.22, 0.46, 0.88, 1.575, 2.80, 5.475, 11.875, 82 (20.925[a])
Pettersson et al. (2014)	0.19, 2.08, 4.345, 34 (9.245[a])

[illegible]

The strength of the association is tied to the magnitude of the response and the statistical significance of that response. For all of these studies, the actual magnitude of the RRs seen in the studies are small, in many cases falling below 1. It is clear from [illegible], that the longer the duration, the larger the mRR and the more statistical significance to the risk.

Laterality matters for addressing the strength of the association. For regular users versus non-regular users, **Interphone (2010)** [67] and **Pettersson et al. (2014)** [162] saw ipsilateral ORs smaller than the contralateral ORs [Note that **Pettersson et al. (2014)** [162] define ipsilateral differently, including people who used both hands in the ipsilateral category]. In contrast, **Corona et al. (2012)** [161] and **Hardell et al. (2013)** [160] saw ipsilateral ORs greater than the contralateral ORs. Laterality seems to become more pronounced with a longer duration of exposure or greater cumulative hours of use in **Interphone (2010)** [67] but not in **Pettersson et al. (2014)** [162].

In the case-case study by **Sato et al. (2014)** [163], they calculated ORs for the grouping left-handed users with left side ANs (l/l) and right-handed users with right-side ANs (r/r) against all miss-matched tumors (l/r and r/l). For a 1-year lag they saw an OR of 1.08 (0.93-1.28) and for a 5-year lag they saw an OR of 1.14 (0.96-1.40). When they examined this for duration of use, they saw generally increasing ORs that were >1, but not statistically significant. For weighted average minutes per day of use, they saw significant ORs for 1-year lag (2.74 [1.18-7.85]) and 5-year lag (3.08 [1.47-7.41]) and significantly increasing ORs for the 5-year lag group (p=0.004). For the average duration of a call, they saw the same basic pattern.

4.2.4 Ecological Epidemiology Studies of Acoustic Neuroma

Benson et al. (2013) [102] examined temporal trends in acoustic neuroma incidence rates in England using data from the UK Office of National Statistics. They restricted their analysis to the years 1998-2008. They provided no analysis of these data, only a plot of incidence over time.

Several studies are also mentioned in Section 1.4.

4.2.5 Conclusions for Acoustic Neuromas

The evidence on an association between cellular phone use and the risk of acoustic neuromas in adults is strong. While there is considerable difference from study to study on ever versus never usage of cellular phones, 3 of the 4 meta-analyses in [illegible] are above 1 although none-significantly. The meta-analyses in Table 14 demonstrate an increased risk in the highest 2 latency groups for the case-control studies that gets slightly higher when the cohort studies are added. For latency ≥5 years, the mRRs are significantly elevated for the case-control studies and the combined case-control and cohort studies. The exposure response meta-regressions in [illegible] indicates that risk is increasing with cumulative hours of exposure, especially in the highest exposure groups. This finding, however, is sensitive to the inclusion of the **Hardell et al. (2013)** [160] study. There is a strong tendency toward ANs appearing on the same side of the head as the phone is generally used, especially as the exposure increases. These findings do not appear to be due to chance. The cohort studies appear to show less of a risk than the case-control studies, but one study is likely to be severely impacted by differential exposure misclassification (**Schuz et al. (2011)** [99]) and the other (**Benson et al. (2013)** [102]) is likely to have a milder differential exposure misclassification. Both studies have very few cases. The case-control studies are possibly impacted by recall bias and this cannot be ruled out for the ANs. Selection bias could have been an issue for **Interphone (2010)** [67], and, unlike their analysis of the glioma data, they have not looked at an alternate referent population for their analyses of AN. Confounding is not an issue here. In conclusion, an association has been established between the use of cellular telephones and the risk of ANs and chance and confounding are unlikely to have driven this finding. Potential recall bias and selection bias may still be an issue with some of these findings.

Laboratory Cancer Studies

There is sufficient evidence from laboratory studies to conclude that RF can cause tumors in experimental animals with strong findings for gliomas, heart Schwannomas and adrenal pheochromocytomas in male rats and harderian gland tumors in male mice and uterine polyps in female mice.

5.1 Chronic Carcinogenicity Studies

5.1.1 Mice

Tillmann et al. (2007) [164] Exposed groups of 50 male and female B6C3F1 mice to four exposure levels (whole body averaged specific absorption rates (SAR) of 0.0, 0.4, 1.3 and 4.0 mW/g) of two different radiofrequency radiation (RF) exposures (902 MHz GSM and 1747

MHz DCS modulated frequencies) for 2 hours per day, 5 days per week for 2 years using head-only exposure in a Ferris wheel/tube-restrained exposure system. The two hours of exposure was done in three phases imitating exposures classified as "basic", "talk" and "environment". All test animals were given a full necropsy and both gross and microscopic lesions identified and characterized. They reported no increases in tumor incidences for any lesion. They did report a significant exposure-related decrease in hepatocellular adenomas in males in the highest exposure group for both GSM (p=0.048) and DCS (p=0.015) exposures. Tumor count data was provided for Pituitary gland, Harderian gland, lungs, liver, adrenals, uterus and hematopoetic/lymphoreticular tissues. Brain tumor data was described as negative but counts were not provided. They reported no difference in survival by treatment group. All data presented were reanalyzed using a one-sided Fisher's exact test for pairwise comparisons and the one-sided exact Armitage linear trend test for increasing or decreasing risk with exposure [165]. The reanalysis showed a decrease in the GSM data in all three treated groups in females in Harderian gland adenomas (p=0.045, <0.01, 0.011; trend test p=0.047), in alveolar/bronchiolar carcinomas at the two lowest exposures (p=0.008, 0.008) and adenomas at the highest exposure (p=0.045), and increased trend in liver adenomas (p=0.033) and a significant increase in uterus endometrial stromal polyps at the two lowest exposures (p=0.004, 0.046) with no increased trend. In the DCS data for females, there was significant effect at the highest exposure for uterus glandular polyps (p=0.013) with a significant trend (p=0.002). In the male GSM exposure groups, Harderian gland adenomas were increased in all groups (p=0.027, 0.003, 0.001) with a significant trend (p=0.004) and a significant decreased trend in liver adenomas (p=0.001) and decreases at all three exposures (p=0.014, 0.014, <0.01). In the male DCS exposure groups, Harderian gland adenomas were decreased for all exposure groups (p=0.001, 0.001, 0.001) with a significant decreased trend (p=0.018), a decrease in liver adenomas at the two highest groups (p=0.03, <0.01) with significant negative trend (p<0.01), and a significant increase in lymphomas in all exposure groups (p=0.004, 0.046, 0.046) with no trend. The increases in Harderian gland adenomas in the male GSM studies may be due to the exposure, but this was not explored by the authors. The large control response for Harderian gland adenomas in males in the DCS exposure studies suggests the incidence for this tumor in these studies is highly variable.

National Toxicology Program (2018) [166] exposed groups of 90 5-6 week old male and female B6C3F1/N mice to sham, GSM-modulated RF (2.5, 5 or 10 W/kg 9 hours/day, 7 days/week) or CDMA-modulated RF (2.5, 5 or 10 W/kg 9 hours/day, 7 days/week) for 106 (males) or 108 (females) weeks. The 9 hours and 10 minutes of exposure was achieved by cycling the fields 10 minutes on and 10 minutes off for 18 hours and 20 minutes each day. The mice exposed GSM-modulated and CDMA-modulated RF used the same sham controls. Exposures were conducted in reverberation chambers and animals were housed in individual cages. Full pathology was conducted on all animals. GSM Study: Survival was significantly higher for the 5 W/kg males than the sham controls; all other groups were not different from controls. There were no body weight differences between exposed animals and controls. They saw a marginal increase in skin fibrosarcoma, sarcoma or malignant fibrous histiocytoma in male mice (p=0.093) (mostly occurring in the tails of these animals), a significant increase in alveolar/bronchiolar adenomas and carcinomas in male mice (p=0.040) but not for adenomas and carcinomas separately, and significant increases in malignant lymphomas in the two lowest exposure groups for females, but the trend test was not significant and the control numbers were substantially smaller than historical controls. To clarify the significance of the lung tumors in males, the NTP historical control data described in the technical report [166] was obtained electronically online, and using Tarone's test for historical controls [167], yields p=0.072. CDMA Study: Survival was significantly higher for the 2.5 W/kg females than the sham controls; all other groups were not different from controls. There were no body weight differences between exposed animals and controls. There were sporadic positive pairwise comparisons that were significant for liver tumors in male mice, but none of these demonstrated any pattern of exposure-response. Also, significant increases in malignant lymphomas in the lowest exposure group for females with increases in all groups, but the trend test was not significantly increased and the control numbers were substantially smaller than historical controls. Two adenomas and 1 carcinoma of the pars distalis in the pituitary gland occurred in the 5 W/kg group but not the other groups (these tumors were not seen in the historical controls). After 14 weeks of exposure, **Smith-Roe et al (2020)** [168] evaluated genotoxicity in several tissues of mice included in these studies for this purpose using the alkaline comet assay (three brain regions, liver, peripheral blood) and the micronucleus assay (peripheral blood). Significant increases in DNA damage were seen in the frontal cortex of male mice (DCMA and GSM) and leukocytes of female mice (CDMA only). NTP uses 5 levels of evidence for classifying the findings of carcinogenicity studies. Equivocal evidence is defined as "*Equivocal evidence of carcinogenic activity is demonstrated by studies that are interpreted as showing a marginal increase of neoplasms that may be test agent related.*" In this study, for GSM-exposed mice, they labeled the skin tumors and lung tumors in males as equivocal and the malignant lymphomas in females as equivocal. For CDMA-exposed mice, they labeled the liver hepatoblastomas in males and the malignant lymphomas in females as equivocal. All of these conclusions seem reasonable. (Note: some text copied directly from **NTP (2018)** [166]).

5.1.2 Rats

Chou et al. (1992) [169] exposed groups of 100 male Sprague-Dawley rats to pulsed microwave radiation at 2450 MHz at 800 pulses per second with a pulse width of 10 µs for 21.5 hours per day, 7 days per week, for 25 months with an appropriate sham control. The exposure was intended to match a military-grade radar system and provide a whole body SAR of about 0.4 w/kg. They saw no changes in survival, body weight, or a number of other measures in the exposed animals and no increased tumor risk in any one organ. They did see a statistically significant increase in total tumors (p<0.001), but it is not clear if this evaluation included multiple findings from the same animal or not (the statistical method used may have been incorrect).

La Regina et al. (2003) [170] exposed groups of 80 male and female Fisher 344 rats (aged 6 weeks) to sham, 835.6 MHz FDMA RF (SAR 1.3 W/kg) or 847.7 MHz CDMA RF (SAR 1.3 W/kg) for 4 hours/day, 5 days/week for 24 months in a tube-restrained Ferris-wheel exposure system. The exposure was predominantly to the head, but all tissues were examined. There were no differences in survival or body weight across appropriate comparison groups. They reported no significant tumor findings.

Anderson et al. (2004) [171] exposed groups of pregnant Fischer 344 rats to RF at 1620 MHz for 2 hours per day, 5 days per week from day 19 of gestation to weaning. At approximately 5 weeks of age, groups of 90 male and female offspring were exposed to the same RF using tubes with predominantly head only exposure for 2 hours per day, 5 days per weeks for 24 months. Targeted head exposure was sham, 0.16 and 1.6 mW/g. They reported no statistically increased differences in reproductive index, litter size, body weight or other clinical signs. There was a slight increase in survival in the highest exposure group in females relative to the sham exposed group. They noted there were no exposure-related significant increases in any tumors and that the highest exposure group of males had a significant increase in mesothelioma of the testis, but that this was within the range of historical controls. A reanalysis of the data presented results in the same findings as those presented by **Anderson et al. (2004)** and also showing a significant trend for mesothelioma of the testis (p=0.003). **Anderson et al. (2004)** compared the oligodentroglioma data in males to the NTP historical control data presented by **Haseman et al. (1990)** [172], however, NTP has a set of controls more closely linked in time to this study that is more appropriate [173] showing the same range of responses (0-2%). Using the range of historical controls is inappropriate in this type of analysis [32, 33, 174] and a direct method of testing, Tarone's historical control test [167], is more appropriate; this test yields a p-value of p<0.001 for the oligodentrogliomas in males. For the mesotheliomas in the testes, the NTP database contains no entries and the source cited by **Anderson et al. (2004)** has a range of 0-2% while the observed response in the highest exposure group was 6/90=6.7%, so well outside the range.

Smith et al. (2007) [175] duplicated the exposure system of **Tillmann et al. (2007)** [164] for groups of 50 male and female Wistar rats. They reported no survival differences and no significant increases in tumors in any tissue evaluated. For the tissues they reported in the paper, a re-analysis using the Armitage linear trend test shows an increase in the incidence of C-cell adenomas in female rats for both GSM (p=0.025) and DCS (p=0.043) exposures, but not for c-cell carcinomas (p=0.50 and p=0.37) and it remains significant for the combined adenomas and carcinomas (p=0.028 and p=0.044).

Bartsch et al. (2010) [176] conducted four separate RF studies in female Sprague-Dawley rats; two long-term (I and II) and two life-long (III and IV) experiments were conducted exposing animals to a low-intensity GSM-like signal (900 MHz pulsed with 217 Hz, 100 µW/cm. average power flux density, 38–80 mW/kg mean specific absorption rate for whole body). Health and survival of unrestrained female Sprague-Dawley rats kept under identical conditions was evaluated. Radiofrequency (RF)-exposure was started at 52–70 days of age and continued for 24 (I), 17 (II) and up to 36 and 37 months, respectively (III/IV). In the first two experiments 12 exposed and 12 sham-exposed animals each were observed until they were maximally 770 or 580 days old (animals either died of natural causes or were sacrificed because they were moribund). In experiment I, no adverse health effects of chronic RF-exposure were detectable, neither by macroscopic nor detailed microscopic pathological examinations. In experiment II no apparent macroscopic pathological changes due to treatment were apparent and microscopic analyses were not conducted. Reductions in pituitary tumors were seen for both experiment I and II but no increases were reported. In experiments III and IV, 30 animals per group showed a significant reduction in survival in the RF-exposed groups relative to the sham-exposed groups and both groups in experiment III showed a significant reduction in survival compared to experiment IV. A reduction in mammary tumors were seen in the RF-exposed animals compared to sham, but this may be due to the survival differences (authors did not evaluate this issue). This study did not perform full pathology, had limited sample sizes and presents very little tumor data.

NTP (2018) [177] exposed groups of 56 time-mated F_0 female Sprague-Dawley rats, housed in specially designed reverberation chambers, to whole-body exposures GSM-modulated cell phone RF or CDMA-modulated RF at power levels of 0 (sham control), 1.5, 3, or 6 W/kg for 7 days per week, continuing throughout gestation and lactation. Exposure was up to 18 hours and 20 minutes per day with continuous cycling of 10 minutes on and 10 minutes off during the exposure periods. At weanling, groups of 90 5-6 week old male and female Sprague-Dawley rats were exposed the same exposures as their F_0 dams for 105 weeks. The rats exposed to GSM-modulated and to CDMA-modulated RF used the same sham controls. Exposures were conducted in reverberation chambers and animals were housed in individual cages. Full pathology was conducted on all animals. GSM Exposures: In F_0 females, there were no exposure-related effects on pregnancy status, maternal survival, or the percentage of animals that littered. During gestation, mean body weight gains of 6 W/kg females were significantly lower than those of the sham controls from GD 15 through 18 and during the overall gestation period (GD 6 through 21). During lactation, the mean body weights of 3 and 6 W/kg females were significantly lower than those of the sham controls for the period of PND 4 through 21. In F_1 offspring, there was no effect on litter size, pup mortality or survival. During lactation, mean pup weights were significantly lower at most timepoints in the 3 W/kg groups and at all timepoints in the 6 W/kg groups. At the end of 2 years, survival of all exposed male groups was significantly greater than that of the sham control group due to the higher severity of chronic progressive nephropathy in the kidney of sham control males (note, almost all male rats had chronic progressive nephropathy). Survival of exposed female groups was similar to that of the sham controls. The mean body weights of all exposed males and females were similar to those of the sham control groups. There were no exposure-related clinical observations. In the heart at the end of the 2-year studies, malignant schwannoma was observed in all exposed male groups and the 3 W/kg female group, but none occurred in the sham controls. Endocardial Schwann cell hyperplasia also occurred in a single 1.5 W/kg male and two 6 W/kg males. There were also significantly increased incidences of right ventricle cardiomyopathy in 3 and 6 W/kg males and females. In the brain of males, there were increased incidences of malignant glioma and glial cell hyperplasia in all exposed groups, but none in the sham controls. There was also increased incidences of benign or malignant granular cell tumors in all exposed groups. There were significantly increased incidences of benign pheochromocytoma and benign, malignant, or complex pheochromocytoma (combined) of the adrenal medulla in males exposed to 1.5 or 3 W/kg. In the adrenal medulla of females exposed to 6 W/kg, there were significantly increased incidences of hyperplasia. In the prostate gland of male rats, there were increased incidences of adenoma or adenoma or carcinoma (combined) in 3 W/kg males and epithelium hyperplasia in all exposed male groups. In the pituitary gland (pars distalis), there were increased incidences of adenoma in all exposed male groups. There were also increased incidences of adenoma or carcinoma (combined) of the pancreatic islets in all exposed groups of male rats, but only the incidence in the 1.5 W/kg group was significant. In female rats, there were significantly increased incidences of C-cell hyperplasia of the thyroid gland in all exposed groups, and significantly increased incidences of hyperplasia of the adrenal cortex in the 3 and 6 W/kg groups. CDMA Exposures: In F_0 females, there were no exposure-related effects on pregnancy status, maternal survival, or the percentage of animals that littered. During gestation, the mean body weights and mean body weight gains of exposed groups were similar to those of the sham controls. During lactation, mean body weights were significantly lower than those of the sham controls at most time points in the 6 W/kg group, at several time points in the 1.5 and 3 W/kg groups, and the mean body weight gains for the period as a whole (PND 1 through 21) were significantly lower in the 3 and 6 W/kg groups. In F_1 offspring, there were no effects on litter size on PND 1. On PND 7 through 21, there were significant decreases in live litter size in the 6 W/kg group when compared to the sham controls. Throughout lactation, the male and female pup mean body weights in the 6 W/kg groups were significantly lower than those of the sham controls. At the end of 2 years, survival in all exposed male groups was greater than that of the sham control group due to the effects of chronic progressive nephropathy in the kidney of the sham control males. In females, there was a small, but statistically significant increase in survival in the 6 W/kg group. Although there were some differences in mean body weights in exposed male groups, at the end of the study, the mean body weights of exposed male and female groups were similar to those of the sham controls. There were no exposure-related clinical observations. At the end of the 2-year study, malignant schwannoma of the heart occurred in all exposed male groups and the incidence in the 6 W/kg group was significantly increased; this neoplasm did not occur in the sham controls. There was also an increased incidence of endocardial Schwann cell hyperplasia in 6 W/kg males. In females, malignant schwannoma occurred in two animals each in the 1.5 and 6 W/kg groups. In the brain, malignant glioma occurred in 6 W/kg males and 1.5 W/kg females; none occurred in the sham control groups. Glial cell hyperplasia also occurred in 1.5 and 6 W/kg males and 3 and 6 W/kg females. In males, there was a significantly increased incidence of pituitary gland (pars distalis) adenoma in the 3 W/kg group, and increased incidences of hepatocellular adenoma or carcinoma (combined) in the liver of all exposed groups. In the adrenal medulla of females, there were increased incidences of benign, malignant, or complex pheochromocytoma (combined) in all exposed groups, but only the incidence in the 1.5 W/kg group was significantly increased compared to the sham controls. In the prostate gland of male rats, there were increased incidences of epithelial hyperplasia in all exposed groups, but only the incidence in the 6 W/kg group was significantly increased compared to the sham control group. After 14 weeks of exposure, **Smith-Roe et al (2020)** [168] evaluated genotoxicity in several tissues of rats included in these studies for this purpose using the alkaline comet assay (three brain regions, liver, peripheral blood) and the micronucleus assay (peripheral blood). Significant increases in DNA damage were seen in the hippocampus of male rats (CDMA-only). For the NTP, clear evidence of carcinogenic activity is "*demonstrated by studies that are interpreted as showing a exposure-related (i) increase of malignant neoplasms, (ii) increase of a combination of malignant and benign neoplasms, or (iii) marked increase of benign neoplasms if there is an indication from this or other studies of the ability of such tumors to progress to malignancy.*" For GSM exposures in males, NTP classified the malignant schwannomas of the heart, the malignant gliomas and the pheochromocytomas of the adrenal medulla as "clear evidence of carcinogenicity" and the granular cell tumors of the meninges, prostate gland tumors, pituitary gland tumors and pancreas islet-cell tumors as "equivocal findings". In females, the NTP classified the malignant schwannomas of the heart as equivocal. For the CDMA exposures in males, NTP classified the malignant schwannomas of the heart and the malignant gliomas as "clear evidence of carcinogenicity" and the pituitary tumors and liver tumors as "equivocal evidence". In females, the NTP classified the malignant schwannomas of the heart, the malignant gliomas and the pheochromocytomas of the adrenal medulla as equivocal. Given the glial hyperplasia, cardiomyopathy in the right ventricle and the magnitude of the effect in the adrenal gland, I agree with the calls by the NTP. It is also worth noting that, when compared to the historical controls (Tarone's test), the lowest exposure CDMA group had a significant (0.016) increase in malignant gliomas. (Note: some text copied from **NTP (2018)** [177]).

Falcioni et al. (2018) [178] exposed groups (number not given) of F_0 female Sprague-Dawley rats, housed in specially designed cages, to whole-body exposures 1.8 GHz GSM-modulated cell phone RF at power levels of 0 (sham control), 5, 25 and 50 V/m for 7 days per week, from PD-12 continuing throughout gestation and lactation. Exposure was for 19 hours per day. At weanling, groups of approximately 200 (highest 2 exposures) or 400 (sham controls and low exposure) 5-6 week old male and female Sprague-Dawley rats were exposed the same exposures as their F_0 dams for 105 weeks (equivalent to 0.001, 0.03 and 0.1 W/kg SAR). Exposures were conducted in circular cage array with an antenna in the middle and animals were housed in individual chambers (5 per cage). Full pathology was conducted on all animals. This report only details the findings in the brain and the heart. They noted non-significant increases in Schwann cell hyperplasia at the high exposure for both males and females and an increase in malignant Schwannomas of the heart in males in the highest treatment group (p=0.037) and, using the Armitage linear trend test, yielded a significant trend (p=0.037). They noted that the rate of schwannomas in untreated males from their historical controls was 19/3160 (0.6%) and they observed 3/207 (1.4%). Heart schwannomas in females showed no trend. There were no increases in premalignant or malignant lesions in the brain for males or females in this study. The females had a slight positive trend in gliomas (p=0.118) but it was clearly not significant.

5.2 Transgenic and Tumor-Prone Models

5.2.1 Eμ-pim1 transgenic mouse

The Eμ-pim1 transgenic mice are prone to getting lymphomas.

Repacholi et al. (1997) [179] exposed groups of 100 to 101 female heterozygous Eμ-pim1 mice to GSM modulated RF at 900 MHz for up to 18 months with SAR values ranging from 0.13 to 1.4 W/kg depending upon animal sizes and the number in a cage. Mice were exposed for 30 minutes twice a day in cages grouped around a central antenna There were no differences in weight by exposure, but there was a difference in deaths prior to study termination with 44/100 sham animals terminated early and 70/101 exposed animals terminated early. They reported a significant increase in the incidence of all lymphomas (p<0.001) and of non-lymphoblastic lymphomas (p=0.002) as a function of exposure. The statistical analysis of the data were unusual with analysis of only animals that died during the course of the study (terminal sacrifice animals were not examined histopathologically) and using a competing risk logistic regression model that is not fully explained in addition to the standard Fisher's exact test. The assumption that animals that did not die prior to terminal sacrifice were free of lymphomas makes this study difficult to interpret.

Utteridge et al. (2002) [180] attempted to replicate the study of Repacholi et al. (1997) [179] but with several differences. They used 120 animals per group, they included groups of wild-type C57BL/6N female mice, their GSM signal was 898.4 MHz, they used a restrained Ferris wheel design, exposed for 1 hour per day, 5 days per week for 104 weeks, and did full histopathological analysis on all mice regardless of survival. They used four different exposure groups at 0.25, 1.0, 2.0 and 4.0 W/kg. No exposure-related differences in body weight or survival were seen. They reported no exposure-related increases in any tumors from this study. The longer duration of this study makes the direct comparison to Repacholi et al. (1997) difficult since most animals in this study had lymphomas at 104 weeks.

Oberto et al. (2007) [181] used the same exposure system as Utteridge et al. (2002) [180] to repeat the study of Repacholi et al. (1997) [179] by exposing groups of 50 male and female heterozygous Eμ-pim1 mice to 900 MHz pulsed RF fields for 18 months at whole-body SAR levels of 0.5, 1.4 and 4.0 W/kg. Exposures were for 30 minutes, twice daily, 7 days per week. Survival was reduced for male mice in all exposures and for female mice exposed at 0.5 W/kg; there were no significant differences in body weights. They reported no significant changes in lymphomas in males or females and a significant increase in Harderian gland adenomas in males that was exposure-dependent (p=0.028). Using the Armitage linear trend test, the data show the change in Harderian gland adenomas in males (p=0.007), liver vascular tumors in males (p=0.015) and lung alveolar/bronchiolar adenomas (p=0.045) in males. The largest difference between Repacholi et al. (1997) (22%) and Oberto et al. (2007) (44%) was in the number of sham controls with lymphomas and this was not due to only looking at decedents since Oberto et al. (2007) provided this analysis as well.

5.2.2 Patched1$^{+/-}$ Mice

The Patched1 heterozygous (Ptc1+/-) knockout mice are prone to getting tumors of the brain and are hypersensitive to ionizing radiation.

Saran et al. (2007) [182] exposed groups of 23-36 male and female Ptc1+/- mice and groups of 22-29 male and female wildtype CD1 mice to 900 MHz RF at whole-body SAR of 0.4 W/kg from postnatal days 2-6 for 30 minutes, twice per day and then followed for their lifespan with full necropsy at death or moribund sacrifice. Exposures were done in a system that constrained the mice during exposure. There were no survival differences with regard to exposure. The authors reported no increases in any tumors as a function of exposure. They reported an increase in Rhabdomyosarcoma in male and female combined in exposed versus sham which was marginally significant when evaluated using the one-sided trend test (p=0.053). This study used a fairly low exposure for a very short exposure window.

5.2.3 AKR/j Mouse

The AKR/j mouse is known to rapidly develop hematopoietic tumors, especially thymic lymphoblastic lymphoma, in the first year of life.

Sommer et al. (2004) [183] exposed groups of 160 female AKR/j mice to either sham or 900 MHz GSM-like RF (0.4 W/kg) for 24 hours/day, 7 days/wk until 46 weeks of age. Mice were housed 6-7 per cage in a Ferris wheel design. There was a significant difference in relative weight change but not in absolute change. There were no survival differences. There were no differences in death from lymphoblastic lymphoma between the sham and RF exposed groups. In a second study using the same design, **Sommer et al. (2007)** [184] used 1966 MHz UMTS RF (0.4 W/kg). There were no significant weight changes, no changes in survival or the incidence of lymphomas although there was a marginal reduction in the number of animals surviving to study end in the RF exposed group (p=0.055).

Lee et al. (2011) [185] exposed groups of 40 male and 40 female AKR/j mice to sham or a combination of 848.5 MHz CDMA (2 W/kg) and 1950 MHz WCDMA (2 W/kg) RF for 45 min/day, 5 days/week for up to 42 weeks. Animals were housed 5 per cage during exposure in a reverberation chamber. No differences in body weight, survival or tumor incidence were observed.

5.2.3 C3H Mice

The C3H mouse carries a virus passed through breast milk that induces tumors of the mammary gland.

Szmigielski et al. (1982) [186] exposed groups of 40 female C3H/HeA mice to 2450 MHz RF from 6 weeks to 12 months at levels of 0, 2-3 W/kg and 6-8 W/kg. Exposure was carried out in an anechoic chamber for 2 hours per day, 6 days per week. The presence of mammary gland tumors was determined by palpation every two weeks. The authors noted a exposure-related increase in the number of mammary tumors ($p<0.01$) and a exposure-related decrease in the time to onset of mammary tumors ($p<0.05$) in their experiments. By their analysis, no other tumors were significantly increased as a function of exposure to the RF.

Toler et al. (1997) [187] exposed groups of 200 female C3H/HeJ mice for 21 months (22 h/day, 7 days/week) to a horizontally polarized 435 MHz pulse-wave (1.0 microsecond pulse width, 1.0 kHz pulse rate) RF environment with an SAR of 0.32 W/kg. An additional 200 mice were sham-exposed. All animals were necropsied and subject to full histpathological analysis. The exposure facility used 50 single housing cages around a central antenna facility to produce uniform circular fields. No survival differences were observed between the groups. There were no significant differences between the two groups with respect to latency to tumor onset, tumor growth rate and overall tumor incidence for mammary tumors. The only significant difference between groups for tumors in other organs was for bilateral ovarian epithelial stromal tumors ($p=0.03$ by their analysis, $p=0.023$ by mine) but became nonsignificant when all animals with stromal tumors were considered ($p=0.24$ by their analysis, $p=0.12$ by mine).

Frei et al. (1998) [188] exposed groups of 100 female C3H/HeJ mice for 18 months to 2450 MHz microwave radiation for 20 hours per day, 7 days per week. Exposure was via the CWG system with 2 animals per cage distributed around a circular field. The SAR targeted in this study was 0.3 W/kg. There were no differences in body weight or survival in the two groups. There were no significant differences between the two groups with respect to latency to tumor onset, tumor growth rate and overall tumor incidence for mammary tumors. There were no significant increases in tumors at any site but they also saw a slight increase in bilateral ovarian stromal tumors. **Frei et al. (1998)** [189] repeated this study using an SAR of 1 W/kg, again seeing no increases in any tumor as a function of exposure. In this second study, mammary tumors in sham-treated animals were much lower (30%) than in the previous study (54%).

Jauchem et al. (2001) [190] exposed groups of 100 female C3H/HeJ mice to pulses composed of an ultra-wideband (UWB) of frequencies, including those in the RF range (rise time 176 ps, fall time 3.5 ns, pulse width 1.9 ns, peak E-field 40 kV/m, repetition rate 1 kHz) at an SAR of 0.0098W/kg for 2 minutes per week for 12 weeks with a follow-up of 64 weeks. They saw no neoplastic changes associated with exposure. [This study uses an incredibly small SAR for a very short period.]

5.3 Initiation-Promotion Studies

In general, initiation promotion studies use two stages of exposure to determine if a particular exposure starts the cancer process (initiates tumors) or makes tumors grow faster or appear more readily (promotion). In most cases in the literature that follows, researchers are testing for the promotional impacts of RF using a known initiator (chemical that starts the cancer process).

5.3.1 Skin Models

The usual initiation-promotion study in skin involves the application of an initiator chemical (7,12-dimethylbenz[a]anthracene (DMBA) or benzo[a]pyrene (BAP)) once to the shaved skin of a mouse followed by frequent exposures to a promotor (in this case RF) for a long period of time. The studies also typically use a known promotor as a positive control (e.g. 12-O-tetradecanoylphorbol-13-acetate or TPA) to demonstrate the experimental setting is working appropriately. The tumors that appear on the back of the animals are tracked over time and the endpoints of interest (tumor frequency and multiplicity) recorded daily.

Chagnaud et al. (1999) [191] exposed groups of 8-18 female Sprague-Dawley rats to GSM 900 MHz RF at an SAR of 75 mW/kg starting 20, 40 or 75 days after initiation by BaP (2 mg) for 2 hours per day, 5 days per week for two weeks. In addition, GSM 900 MHz RF at an SAR of 270 mW/kg was administered 40 days after exposure to BaP (2 mg) for 2 hours per day, 5 days per week for two weeks. The study was terminated approximately 160 days after the BaP exposure. There was no impact of any RF exposure on the survival or time to tumor in these experiments.

Mason et al. (2001) [192] exposed groups of 27-55 female Sencar rats to DMBA (initiator, 2.56 µg) followed by a single 10 second exposure to 94 GHz RF at 1 W/cm^2 or to infrared radiation (IR) at 1.5 W/cm^2, both designed to raise skin temperature by 13-15° C. The animals were followed for 23 weeks and there was no indication of a promotion affect on these animals. In a second experiment using the same basic protocol, exposures of 10 seconds twice per week for 12 weeks to RF at 333 mW/cm^2 and IR at 600 mW/cm^2 (designed to raise skin temperature by 4-5° C) and followed to 25 weeks. There was no indication of a promotion effect of RF in this experiment. The authors also conducted a co-promotional study where the RF and IR exposures were given along with TPA to see if the RF enhanced the TPA promotional effect; this study was also negative.

Imaida et al. (2001) [193] exposed exposed groups of 48 female ICR mice to DMBA (initiator, 100 µg) followed by a TDMA RF field at 1.49 GHz (50 pulse per second) for 90 minutes per day, 5 days per week for 19 weeks at an SAR of 2 W/kg. There was no promotion of tumors by RF in this study.

Huang et al. (2005) [194] exposed a group of 20 male ICR mice to DMBA (initiator, 100 µg) followed by a CDMA signal at 849 MHz for 45 minutes twice per day, 5 days per week for 19 weeks at an SAR of 0.4 W/kg. They exposed a second group of 20 males to CDMA signal at 1763 MHz for 45 minutes twice per day, 5 days per week for 19 weeks at an SAR of 0.4 W/kg. There was no promotion of tumors by RF in this study.

Paulraj and Behari (2011) [195] exposed groups of 10 male Swiss albino mice to DMBA (initiator, 100 µg) to 112 MHz amplitude modulated (AM) at 16 Hz (power density 1.0 mW/cm^2, SAR 0.75 W/kg) or to 2.45 GHz radiation (power density of 0.34 mW/cm2, SAR, 0.1 W/kg), 2 h/day, 3 days a week for a period of 16 weeks. There was no promotion of tumors by RF in this study. In a second experiment, mice were transplanted intraperitoneally (ip) with ascites $8x10^8$ (Ehrlich-Lettre ascites, strain E) carcinoma cells per mouse followed by the same 2 radiation exposures for 14 days. They saw a non-significant increase in the number of ascites in the treated groups compared to the appropriate controls. This study suffers from a very small sample size.

5.3.2 Lymphoma Models

Here, the initiator is ionizing radiation.

Heikkinen et al. (2001) [196] exposed groups of 50 female CBA/S mice to Xrays (initiation, 4-6 MV, 3 weekly exposures of 1.333 Gy) followed by exposure to NMT900-type frequency-modulated RF at 902.5 MHz and a nominal SAR of 1.5 W/kg for 1.5 hours/day, 5 days per week, for 78 weeks. A second group with the same initiation was exposed to GSM-type RF at 902.5 MHz (pulse frequency 217 Hz) at an SAR of 0.35 W/kg with the same exposure pattern. They saw a increase in the median corpuscular hemoglobin concentration in both RF exposure groups (p=0.008 NMT900 and p=0.026 GSM). There were no survival differences. There were several changes in preneoplastic hyperplastic markers related to RF exposure, but no significant increases in tumors related to RF. There was a significant reduction in pheochromocytomas in the adrenal glands in both RF exposure groups. There were no changes in lymphoma incidence.

5.3.3 Mammary-gland Tumor Model

This model typically involves female Sprague-Dawley rats initiated by DMBA.

Bartsch et al. (2002) [197] sequentially conducted three identical studies where groups of 60 female Sprague-Dawley rats were given DMBA as an initiator (50 mg/kg/day) followed by either sham exposure or exposure to GSM RF at 900 MHz (pulse 217 Hz) for 23 hours per day, 7 days per week for 259-334 days. Exposures were in group-housed cages and ranged from 15 to 130 mW/kg depending upon the age of the animals. There were no differences between sham and exposed animals in terms of numbers of benign or malignant tumors at study termination in all three experiments although the experiments themselves differed significantly in overall tumor incidence. In the first experiment, malignant mammary tumors appeared much more rapidly in sham-exposed animals, but this was not reproduced in the two replicates.

Anane et al. (2003) [198] conducted 2 experiments using a GSM signal at 900 MHz with female Sprague-Dawley rats in cages in a chamber for 2 hours/day, 5 days/week for 9 weeks and followed without exposure for 2 more weeks. Initiation was done using DMBA (10 mg) and RF exposures began 10 days after initiation. In the first exposure, 16 animals per group were exposed to 0, 1.4, 2.2 or 3.5 W/kg SAR RF and in the second were exposed to 0, 0.1, 0.7 and 1.4 W/kg SAR RF. The first experiment saw a reduction in time to tumor for the 1.4 W/kg group, a lesser, but still significant reduction in time to malignant tumor for the 2.2 W/kg group and no difference from sham-exposed for the 3.5 W/kg group. This was not seen in the second experiment. The second experiment also saw substantially reduced tumor counts in the treated groups compared to the first experiment.

Yu et al. (2006) [199] exposed four groups of 99-100 female Sprague-Dawley rats to DMBA (initiator, 35 mg/kg) followed by sham exposure or exposure to 900MHz GSM signal RF for 4 hours/day, 5 days/week for 26 weeks in a Ferris wheel tube-restrained exposure system. The four exposures were 0, 0.44, 1.33 and 4.0 W/kg SAR. No differences in body weight, incidence, latency, multiplicity or size of mammary gland tumors was seen in this experiment as a function of RF exposure.

Hruby et al. (2008) [200] conducted an experiment almost identical to that of Yu et al. (2006). Four groups of 100 female Sprague-Dawley rats were exposed to DMBA (initiator, 17 mg/kg) followed by sham exposure or exposure to 900MHz GSM signal RF for 4 hours/day, 5 days/week for 26 weeks in a Ferris wheel tube-restrained exposure system. The four exposures were 0, 0.4, 1.3 and 4.0 W/kg SAR. The results showed a significant shift from benign mammary tumors to malignant mammary tumors for animals with exposure to RF. The highest exposure group saw a significant increase in malignant tumors relative to the sham controls and all three RF exposure groups saw a significant reduction in benign tumors compared to the sham exposure group. No differences in volume or time-to-palpable tumor were seen.

5.3.4 Brain tumor models

Brain tumor initiation-promotion studies generally use rats (Fischer 344 or Sprague-Dawley) initiated for brain tumors using N-ethyl-N-nitrosourea (ENU) in-utero using a single intravenous exposure to the dam.

Adey et al. (1999) [201] exposed two groups of 9 pregnant Fisher 344 rats to ENU (4 mg/kg) on day 18 of gestation and two groups of 9 to sham exposure. Starting on day 19 of gestation to post-natal day (PND) 21, two groups of dams and offspring (one with ENU [denoted EF for ENU-Field] and the other without [denoted SF for Sham-Field]) were exposed in cages to far field TDMA (836.55 MHz) for 2 hours/day, 7 days/week (SAR not provided) and two groups (no enu [denoted SS] and with ENU [denoted ES]) were given smam exposure to RF. Starting on PND 33 until two years of age, groups of 30 male and 30 female mice were exposed to near-field TDMA exposures at 836.55 MHz in the same groups as with the dams (SS, ES, SF, EF). Near field exposures (animals held in tubes with predominantly head exposure) had an SAR from 1.1-1.6 W/kg. Animals administered ENU had a reduction in survival in all groups and animals with RF exposure survived longer than their respective controls in all groups (not statistically significant). All RF exposed groups had reduced central nervous system tumors relative to their appropriate controls except for meningiomas (without ENU there was 1 tumor in RF exposed and no tumors in control and with ENU there were 2 tumors in RF exposed and none in control) and granular cell tumors (without ENU there was 1 tumor in RF exposed and no tumors in control). A reanalysis of the data using the exact trend statistic (one-sided) shows a significant reduction in CNS tumors with RF exposure with ($p=0.036$) and without ($p=0.016$) ENU, almost entirely due to glial tumors. No numbers were provided for any differences by sex.

Adey et al. (2000) [202] repeated this study with a larger number of offspring (45 males and 45 females) in each of the exposure groups and using an FM signal (836.55 MHz). The survival patterns were the same as for their previous study. Unlike the previous study, RF exposure yielded approximately the same incidence as sham exposure for all CNS and brain tumors. Differences between sexes were not provided.

Zook and Simmens (2001) [203] exposed pregnant female Sprague-Dawley rats to ENU at a exposure of 0, 2.5 or 10 mg/kg on day 15 of gestation. At 8 weeks of age, groups of 30 male and 30 female rats with in-utero ENU exposure were exposed to sham, pulsed-wave RF exposure (860 MHz) at a brain SAR of 1 W/kg or pulsed-wave RF exposure (860 MHz) at a brain SAR of 1 W/kg for 6 hours per day, 4 days per week for 22 months. The exposure was 'head only' and used a tube-restrained system in a Ferris wheel design. Results were presented for males and females combined. There were no significant findings in the brain or central nervous system. There was a significant increase in thyroid tumors in males (p=0.016, all sham controls grouped and all ENU exposures grouped) and a marginal increase in female mammary tumors (p=0.057).

Zook and Simmons (2006) [204] repeated this experiment where they exposed pregnant female Sprague-Dawley rats to ENU at a exposure of 6.35 or 10 mg/kg on day 15 of gestation. At 8 weeks of age, groups of 90 male and 90 female rats with in-utero ENU exposure were exposed to sham or pulsed-wave RF exposure (860 MHz) at a brain SAR of 1 W/kg for 6 hours per day, 4 days per week for 22 months. The exposure was 'head only' and used a tube-restrained system in a Ferris wheel design. Results were presented for males and females combined. There were no significant findings in the brain or central nervous system.

Shirai et al. (2005) [205] exposed pregnant female Fisher 344 rats to ENU as done in Adey et al. (1999). At 5 weeks of age, groups of 50 male and 50 female rats with in-utero ENU exposure were exposed to sham, TDMA RF exposure (1439 MHz) at a brain SAR of 0.67 W/kg or at a brain SAR of 2 W/kg for 90 minutes per day, 5 days per week until age 104 weeks. The exposure was "head only" as in **Adey et al. (1999)**. In females, there was a non-significant increase in survival with RF exposure but not in males. The authors reported no significant changes in any CNS tumors in the RF-exposed animals relative to sham-exposed animals. However, a reanalysis of the data using the Armitage linear trend test shows a marginal decrease in any type of brain tumor in females (p=0.057) that is driven by a reduction in astrocytomas (p=0.032). This was not seen in males. They noted a significant reduction in pituitary tumors in the highest exposure group for males, but tumor numbers were not provided.

Shirai et al. (2007) [206] used the exact same exposure scenario to examine the effects of WCDMA RF at 1.95 GHz at SAR 0.67 W/kg and 2.0 W/kg. There were no obvious survival differences among the treated groups and the sham controls and some mild organ weight differences in females but none in males. The authors reported no significant changes in tumor rates for any organ however they did not do trend tests. Using the Armitage linear trend test, female rats saw a significant increase in any brain tumor (p=0.030) driven primarily by an increase in astrocytomas (p=0.027). Males saw an increase in astrocytomas that was not statistically significant (p=0.181).

5.3.5 Liver Tumor Models

Imaida et al. (1998) [207] exposed groups of 48 five-week old male Fisher 344 rats to a single exposure of 200 mg/kg diethylnitrosamine (DEN) followed two-weeks later by exposure to 1.439 GHz TDMA RF at a whole body SAR of 0.453-0.680 W/kg 90 minutes a day, 5 days/week for six weeks. At three weeks the rats received a 2/3 partial hepatectomy and at the end of the six weeks of RF exposure, the study was terminated and all rats examined in their liver for the number and size of glutathione S-transferase placental form positive focal lesions that are considered precursors for liver cancer. They saw significant increases in corticosterone ($p<0.001$), melatonin ($p<0.05$) and adrenocorticotropic hormone ($p<0.001$) and a significant reduction ($p<0.05$) in the number of GST-positive foci/cm2. Similar findings were seen for the exact same experimental design using 929.2 MHz TMDA RF with whole body SARS between 0.58-0.80 W/kg [208].

5.4 Co-Carcinogenesis

Co-carcinogenesis studies are conducted by administering RF exposure along with another substance already known to be carcinogenic to see if the RF exposure enhances the carcinogenic findings. Usually, these models are targeted to a specific type of cancer.

Szmigielski et al. (1982) [186] exposed groups of 40 6-week old male Balb/c mice to 5% solution of 3,4-benzopyrene (BP) on depilated skin every second day for 5 months. Groups of these mice were exposed to 2450 MHz microwaves for 2 hours/day for the same 5 months at exposure of 5 mW/cm2 or 15 mW/cm2. Two other groups of mice were exposed to 1 or 3 months of the same RF exposure of 5 mW/cm2 followed by exposure to BP until 5 months. All animals were observed until 10 months. Exposures were in anechoic chamber. The target of these exposures was skin tumors. There were clear exposure-related and age-related increases in skin tumors in all RF-exposed groups compared to their sham-exposed groups. It is not clear if the sham-exposed controls in the 1- and 3-month RF exposure experiments were properly done. In addition, the presentation of the results from this study are sufficiently confusing that misinterpretation of the findings is possible.

Szudzinski et al. (1982) [209] performed a similar experiment to that done by Szmigielski et al. (1982) (they are in the same research group). They exposed groups of 100 6-week old male Balb/c mice to 1% solution of 3,4-benzopyrene (BP) on depilated skin every second day for 6 months. Groups of these mice were exposed to 2450 MHz microwaves for 2 hours/day for the same 6 months at exposures of 2 mW/cm2 or 6 mW/cm2. Three other groups of mice were exposed to 1, 2 or 3 months of the same RF exposure of 4 mW/cm2 followed by exposure to BP until 6 months. All animals were observed until 10 months of age. Exposures were in anechoic chambers. The target of these exposures was skin tumors. There were clear exposure-related and age-related increases in skin tumors in all RF-exposed groups compared to their sham-exposed groups. It is not clear the sham-exposed controls in the 1-, 2- and 3-month RF exposure experiments were properly done. In addition, the presentation of the results from this study are sufficiently confusing that misinterpretation of the findings is possible.

Wu et al. (1994) [210] exposed two groups of 26-32 male and 26-32 female BALB/c mice to dimethylhydrazine for 14 weeks (15 mg/kg subcutaneous injection oncer per week) and then an additional 8 weeks (20 mg/kg subcutaneous injection oncer per week). Three weeks after the first injection, one groups of mice was sham exposed and the other exposed to 2450 MHz RF (10-12 W/kg SAR) for 3 hours/day, 6 days/week for 5 months. The focus was on colon tumors and there was no difference between groups.

Heikennen et al. (2003) [211] exposed groups of female K2 transgemic mice (overexpressing human ornithine decarboxylase gene) and their wild-type littermates (strain not provided) were exposed to UV radiation (240 J/m2) 3 times per week for 52 weeks. The separate groups were exposed to sham RF, D-AMPS RF (849 MHz, 0.5 W/kg SAR) or GSM RF (902.4

MHz, 0.5 W/kg SAR) 1.5 hours/day, 5 days/week for 52 weeks. The target of the experiment was skin lesions. There were no survival differences when compared to appropriate controls in transgenic or wild-type RF-treated animals and no changes in skin lesion incidence was observed.

Heikennen et al. (2006) [212] exposed groups of 72 female Wistar rats (age 7 weeks) to 3-chloro-4-(dichloromethyl)-5-hydroxy-2(5H)-furanone (MX) via drinking water at a exposure of 1.7 mg/kg/day for 104 weeks. Separate groups were exposed to pulsed RF at 900 MHz (pule frequency 217 Hz) in a circular array of small cages for 2 hours per day, 5 days per week, for 104 weeks at whole body SARs of 0 (sham), 0.3 or 0.9 W/kg. There were no survival differences, body weight gain differences or MX consumption differences between sham-exposed and RF-exposed rats. By Peto's test, the combined incidence of vascular tumors in the mesenteric lymph nodes was significantly increased in trend (p=0.036). Using the Armitage linear trend test, the combined incidence was also significant (p=0.001, one-sided) driven by the increase in hemangiomas (p=0.023). The authors argued this was not significant since the incidence in the cage controls was higher than the sham controls. There was a significant increase in vacuolated foci in the liver by the Armitage linear trend test (p=0.002) but no increases in tumors in the liver.

Tillmann et al. (2010) [213] exposed pregnant B6C3F1 mice and 54-60 of their female offspring to whole-body UMTS RF at 1966 MHz (4.8 W/m2 or 48 W/m2) from GD6 to 2 years of age. The dams exposed to 4.8 W/m2 also received a exposure of 40 mg/kg ENU on GD 14 as did a group with sham exposure to the RF. A full necropsy was performed on each animal. No differences in survival were seen between RF-exposed groups and their appropriate controls. The 48 W/m2 group did not show any increases in tumors relative to the appropriate controls although they did see a significant increase in liver focal lesions (p=0.002 one-sided). The ENU-treated groups were terminated after 75 weeks due to mortality and all animals necropsied. The RF-exposed group saw an increase in bronchiolar-alveolar carcinomas (p=0.005), adenomas (p=0.032), adenomas or carcinomas combined (0.017) and a marginal increase in hyperplasias (p=0.098). They also saw an increase in liver adenomas (p<0.001), not carcinomas or blastomas, but an increase in combined adenomas/carcinomas/blastomas (p=0.023) and an increase in liver foci (p=0.005). There were no increases in brain tumors in any treated groups. Tumor multiplicity in both the lung and the liver was increased as was the incidence of metastasizing lung tumors.

5.5 Summary and Conclusions for Laboratory Cancer Studies

The central question to ask of animal cancer studies is "Can RF increase the incidence of tumors in laboratory animals?" The answer, with high confidence, is yes. Table 20 summarizes the findings from the chronic exposure carcinogenicity studies for RF.

For rats, the **NTP (2018)** [177] chronic exposure bioassay in male Sprague-Dawley rats, including in-utero exposure, is clearly positive for acoustic neuromas of the heart, malignant gliomas of the brain and pheochromocytomas of the adrenal gland. These findings are further supported by the presence of preneoplastic lesions and tissue toxicity in the heart, brain glial cells and adrenal glands. The less convincing findings in the study by **Falcioni et al. (2018)** [178] of heart acoustic neuromas in male Sprague-Dawley rats and a marginal increase in malignant gliomas in females provides additional support for this finding. The study by **Anderson et al. (2004)** [171] with a significant increase in oligodentrogliomas in male Fischer 344 rats when compared against historical controls provides additional strong support for an increase in gliomas from exposure to RF. This study also saw an increase in testis mesothelioma which may have been due to exposure. The lack of any brain pathology or tumors in any organ or tissue within the study by **La Regina et al. (2003)** [170], which was also in Fischer 344 rats, weakens the findings from the Anderson et al. (2004) study, but cannot fully negate them since these are different exposures at different frequencies. The **Bartsch et al. (2010)** [176] study, done using Sprague-Dawley rats, is too limited to challenge the findings of the **NTP (2018)** study. Finally, the lack of brain and heart tumors in the **Smith et al. (2007)** [175] study, done in Wistar rats, could easily be due to the different strain of rat. This study did see an exposure-related increase in thyroid C-cell tumors that was not seen in the other studies in rats.

In B6C3F$_1$ mice (the only strain tested for chronic exposure), the strongest findings are for the Harderian gland tumors in males for GSM but not DCS RF and the increase in uterine polyps in females for both GSM and DCS in the **Tillmann et al. (2007)** study [164] and the increase in rare tumors of the pars distalis in the pituitary of females in the **NTP (2018)** [166] study which were also seen for the male rats in the other NTP study [177]. The variability of the Harderian gland increases and decreases between males and females and the different types of RF in the **Tillmann et al. (2007)** study suggest that the Harderian gland is a sensitive target in these animals or that the response is highly variable in these mice for these tumors. The NTP historical controls [214] for Harderian gland tumors for this period include 29 studies and range between 6% and 26% with a mean of 16% for adenomas and carcinomas combined; the exposed groups in the **Tillmann et al. (2007)** GSM study showed responses of 24%, 32% and 36% for the low, medium and high male exposure groups, beyond the range of the historical control data supporting the conclusion this is a real, exposure-related finding. The **NTP (2018)** study did not see an increase in Harderian gland tumors in males nor an increase in uterine polyps in females. However, this study used a very different exposure system and this may have contributed to the differences.

The studies in transgenic and tumor-prone mice show mixed results. The initial positive finding of lymphomas in Eμ-pim1 transgenic mice by **Repacholli et al. (1997)** [179] were not seen in two subsequent studies [180, 181] that used better designs and better methods. It is interesting to note that the **Oberto et al. (2007)** study [181] saw an increase in Harderian gland tumors in male mice, supporting the finding from **Tillmann et al. (2007)** [164]. The one study in Patched1+/- transgenic mice was negative for brain tumors but saw a marginal increase in Rhabdomyosarcomas. The two studies in AKR/j mice were negative. The study with the highest SAR exposure levels in C3H mice [186] was positive for mammary tumors, but the remaining four [187-190] were not. It is of note that two of these studies [187, 188] saw increases in uterine stromal polyps supporting the findings from **Tillmann et al. (2007)** [164].

The initiation-promotion studies in skin [191-195] were uniformly negative as was the one study using a lymphoma model [196]. The initiation-promotion studies using a mammary tumor model [197-200] were also uniformly negative although the study by **Hruby et al. (2006)** [200] saw an exposure-related shift from benign mammary tumors to malignant tumors. The initiation-promotion studies using ENU-based brain tumor models [201-206] were negative for brain tumors with the exception of one study [206] showing an increase in brain tumors driven by an increase in astrocytomas. One of these studies [203] saw an increase in thyroid tumors in males as a function of exposure that supports the one finding in the chronic study by **Smith et al. (2007)** [175] who saw an increase in thyroid tumors in females. The one initiation-promotion study using a liver tumor model [207] saw increases in liver foci and several changes in endocrine hormones, but no liver tumors.

Four of the co-carcinogenesis studies were positive [186, 209, 212, 213] and two were negative [210, 211]. Two of the positive studies [186, 209] showed skin tumors (not surprising since the co-carcinogen was BP applied to the skin) and another positive study [212] showed increases in lymph nodes and blood vessel tumors. Another positive study [213] saw increases in lung tumors and liver tumors in female mice exposed in-utero supporting findings seen in the **Tillmann et al. (2007)** [164] study and the **NTP (2018)** [166] study.

In conclusion, there is sufficient evidence from these laboratory studies to conclude that RF can cause tumors in experimental animals with strong findings for gliomas, heart Schwannomas and adrenal pheochromocytomas in male rats and harderian gland tumors in male mice and uterine polyps in female mice. There is also some evidence supporting liver tumors and lung tumors in male and possibly female mice.

Table 30: Summary of Chronic Exposure Carcinogenicity Studies for Radiofrequency Radiation

Study	Species/Strain	RF Exposure	Sex	Tumor Finding	Notes
Tillmann et al. (2007) [164]	Mouse B6C3F1	GSM 902 MHz	M	Harderian Gland ^ Liver Adenoma ↓	
			F	Harderian Gland ⌄ Lung Tumors ↓ Liver adenomas^ Uterus polyps ^	All exposures, no trend Two lowest exposures, no trend
		DCS 1747 MHz	M	Harderian Gland ⌄ Liver Adenoma ↓ Lymphomas ↑	All exposure groups, no trend
			F	Uterus polyps ^	
National Toxicology Program (2018) [166]	Mouse B6C3F1	GSM 1.9 GHz	M	Lung tumors ↑	
			F	Malignant lymphomas ↑	Lowest 2 exposures, no trend
		CDMA 1.9 GHz	M	Liver tumors ↑	Sporadic, no trend or pattern
			F	Malignant lymphomas ↑ Pituitary pars distalis ^	Low group, increased in all, no trend Rare tumor
Chou et al. (1992) [169]	Rats S-D	Pulsed 2450 MHz	M	Total tumors ↑	No individual tumor findings
La Regina et al. (2003) [170]	Rats F344	FDMA 835.6 MHz	M		No tumor findings
			F		No tumor findings
		CDMA 847.7 MHz	M		No tumor findings
			F		No tumor findings
Anderson et al. (2004) [171]	Rats F344	Iridium 1.62 GHz	M	Testis mesothelioma ^ Oligodentroglioma ↑	Using HC, p<0.001
			F		No tumor findings
	Rats	GSM	M		No tumor findings

Smith et al. (2007) [175]	Wistar	902 MHz	F	C-cell tumors ↑	Adenomas & combined, not carc.
		DCS	M		No tumor findings
		1747 MHz	F	C-cell tumors ↑	Adenomas & combined, not carc.
Bartsch et al. (2010) [176]	Rats S-D	GSM 900 MHz	F		No tumor findings (four separate experiments, small sample sizes, not full pathology)
NTP (2018) [177]	Rats S-D	GSM 900 MHz	M	Heart schwannoma ^	
				Brain glioma ↑	Rare tumor, biological call
				Adrenal pheochromocytoma ↑	Lowest 2 exposures, no trend
				Brain meninges ^	Biological call
				Prostate gland ↑	Rare tumor, biological call
				Pituitary pars distalis ^	No trend, extensive hyperplasia
				Pancreas islets ^	Low exposure group, no trend
			F	Heart schwannoma ^	One exposure only, rare tumor
		CDMA 900 MHz	M	Heart schwannoma ^	
				Brain glioma ↑	Rare tumor, biological call
				Pituitary pars distalis ^	One exposure, no trend
				Liver tumors ^F	Rare tumor, increased but not significant
				Heart schwannoma ^	Marginal finding
				Brain glioma ↑	Rare tumor, 3 in lowest group, no sig, no trend
				Adrenal pheochromocytoma ↑	Low exposure only, no trend
Falcioni et al. (2018) [178]	Rats S-D	GSM 1.8 GHz	M	Heart schwannoma ^	No tumor findings (slight ↑ in malignant gliomas)
			F		

6. Mechanisms Related to Carcinogenicity

There is sufficient evidence to suggest that both oxidative stress and genotoxicity are caused by exposure to RF and that these mechanisms could be the reason why RF can induce cancer in humans.

6.1 Introduction

Many human carcinogens act via a variety of mechanisms causing various biological changes, taking cells through multiple stages from functioning normally to becoming invasive with little or no growth control (carcinogenic). **Hanahan and Weinberg (2011)**[215] identified morphological changes in cells as they progress though this multistage process and correlated these with genetic alterations to develop what they refer to as the "hallmarks of cancer." These hallmarks deal with the entire process of carcinogenesis and not necessarily with the reasons that cells begin this process or the early stages in the process where normal protective systems within the cells remove potentially cancerous cells from the body. While tumors that arise from a chemical insult to the cell may be distinct from other tumors by mutational analysis, they all exhibit the hallmarks as described by **Hanahan and Weinberg (2011)**.

Systematic review of all data on the mechanisms by which a chemical causes cancer is complicated by the absence of widely accepted methods for evaluating mechanistic data to arrive at an objective conclusion on human hazards associated with carcinogenesis. Such systematic methods exist in other contexts [216], but are only now being accepted as a means of evaluating literature in toxicological evaluations [32, 217-220].

In this portion of the report, I am focusing on the mechanisms that can cause cancer. **Smith et al. (2015)** [39] discussed the use of systematic review methods in identifying and using key information from the literature to characterize the mechanisms by which a chemical causes cancer. They identified 10 "Key Characteristics of Cancer" useful in facilitating a systematic and uniform approach to evaluating mechanistic data relevant to carcinogens. These 10 characteristics are presented in Table 21 (copied from Table 1 of **Smith et al. (2015)** [39]). While there is limited evidence on RF exposure for most of the key characteristics, genotoxicity (characteristic two) and oxidative stress (characteristic five) have sufficient evidence to warrant a full review.

Table 21: Key characteristics of carcinogens, Smith et al. (2016)[65]

Characteristic	Examples of relevant evidence
1. Is electrophilic or can be metabolically activated	Parent compound or metabolite with an electrophilic structure (e.g., epoxide, quinone), formation of DNA and protein adducts
2. Is genotoxic	DNA damage (DNA strand breaks, DNA–protein cross-links, unscheduled DNA synthesis), intercalation, gene mutations, cytogenetic changes (e.g., chromosome aberrations, micronuclei)

3. Alters DNA repair or causes genomic instability	Alterations of DNA replication or repair (e.g., topoisomerase II, base-excision or double-strand break repair)
4. Induces epigenetic alterations	DNA methylation, histone modification, microRNA expression
5. Induces oxidative stress	Oxygen radicals, oxidative stress, oxidative damage to macromolecules (e.g., DNA, lipids)
6. Induces chronic inflammation	Elevated white blood cells, myeloperoxidase activity, altered cytokine and/or chemokine production
7. Is immunosuppressive	Decreased immunosurveillance, immune system dysfunction
8. Modulates receptor-mediated effects	Receptor in/activation (e.g., ER, PPAR, AhR) or modulation of endogenous ligands (including hormones)
9. Causes immortalization	Inhibition of senescence, cell transformation
10. Alters cell proliferation, cell death or nutrient supply	Increased proliferation, decreased apoptosis, changes in growth factors, energetics and signaling pathways related to cellular replication or cell cycle control, angiogenesis

Abbreviations: AhR, aryl hydrocarbon receptor; ER, estrogen receptor; PPAR, peroxisome proliferator-activated receptor. Any of the 10 characteristics in this table could interact with any other (e.g., oxidative stress, DNA damage, and chronic inflammation), which when combined provides stronger evidence for a cancer mechanism than would oxidative stress alone.

6.2 Oxidative Stress

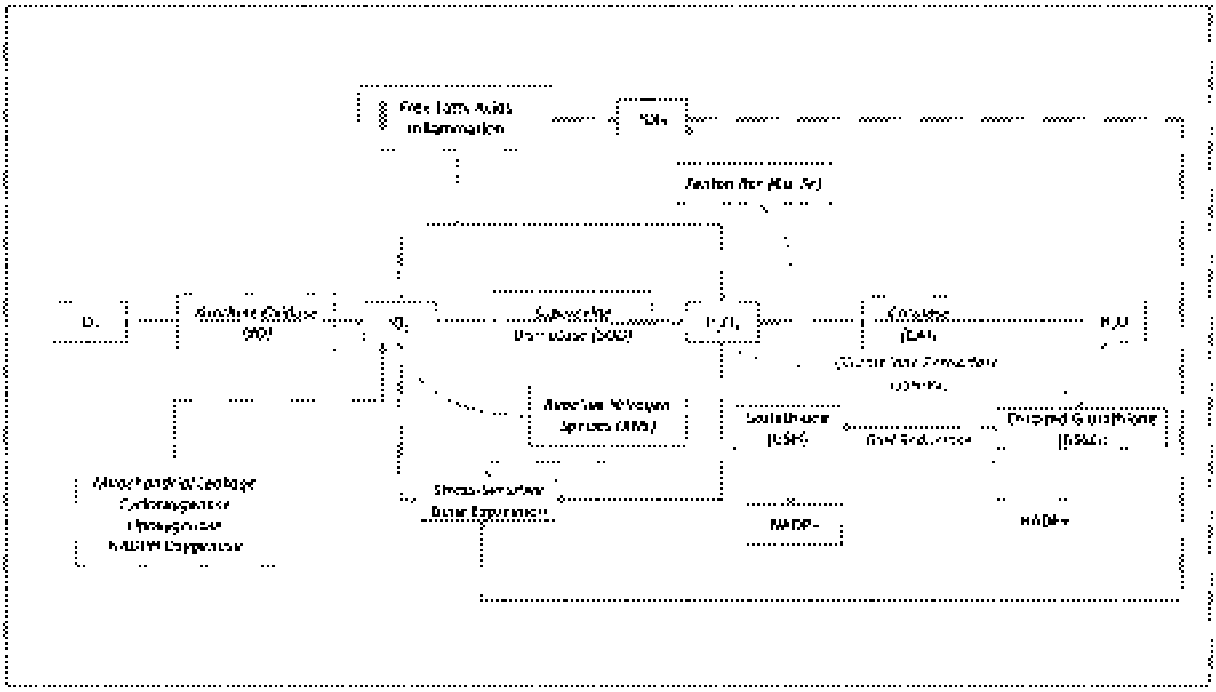
6.2.1 Introduction

Oxidative stress refers to an imbalance between the production of reactive oxygen species (free radicals) in a cell and the antioxidant defenses the cell has in place to prevent this. Oxidative stress has been linked to both the causes and consequences of several diseases [221-226] including cancer [39, 227-231]. Multiple biomarkers exist for oxidative stress; the most common being increased antioxidant enzyme activity, depletion of glutathione or increases in lipid peroxidation. In addition, many studies evaluating oxidative stress used antioxidants following exposure to RF to demonstrate that the effect of the oxidative stress can be diminished.

Measuring oxidative stress can be difficult due to redundant pathways of a highly interconnected system. Molecular oxygen is essential to the proper function of a cell. During the course of normal oxidative phosphorylation, between 0.4 and 4% of all oxygen consumed is converted into the free radical superoxide ($^{\bullet}O_2$). This $^{\bullet}O_2$ can be converted into other ROS and reactive nitrogen species (RNS) and is normally eliminated by antioxidant defenses. $^{\bullet}O_2$ molecules are quickly converted to hydrogen peroxide (H_2O_2) by superoxide dismutase (SOD). H_2O_2 is then either detoxified to H_2O and O_2 by glutathione peroxidase or diffuses into the cytosol and is detoxified by catalase. However, in the presence of reduced transition metals such as copper (Cu) or iron (Fe), H_2O_2 can be converted to the highly reactive hydroxyl radical ($^{\bullet}OH$). These linkages are illustrated in Figure 5.

The three reactive oxygen species (ROS) in the cell ($^{\bullet}O_2$, $^{\bullet}OH$, H_2O_2) can be measured directly, changes in the activity of the major enzymes (XO, SOD, CAT, GSH-Px, GSH reductase) can be measured, changes in GSH or GSSG can be measured, changes in gene expression can be measured, changes in nitrogen oxide (NO) can be measured and changes in other enzymes (e.g. cyclooxygenase) can be measured. No one study measures all of these components. Most studies measure two or more components of this system in animals or cells exposed to RF to see if they have changed due to the RF exposure.

[illegible] Exogenous and endogenous stimuli leading to ROS generation and activation of stress-sensitive gene expression. (modified from [232])



6.2.2 International Agency for Research on Cancer (IARC)

The IARC reviewed the potential for carcinogenicity from RF in 2011 [35]. They evaluated the scientific literature prior to 2011 and concluded "there was weak evidence that exposure to RF radiation affects oxidative stress and alters the levels of reactive oxygen species." This conclusion was driven by methodological shortcomings in the studies, lack of a sham-controlled group in some studies, use of mobile phones for exposures and poor dosimetry. Having looked over the IARC review (I was an *Invited Specialist*[a] for this review), I agree with their assessment of these data and will not discuss any studies prior to 2010.

[illegible] (2011-2020)

[illegible]

Five studies evaluated the effects of RF on humans, two studies using blood, two using saliva and one using seminal plasma. Gulati et al. (2018) [232] compared 116 individuals in India living near cellular towers to 106 controls living more than 800 meters from towers. They saw significant decreases in SOD, CAT and a significant increase in lipid-peroxidation

[a] *Invited Specialists* are experts who have critical knowledge and experience 3 but who also have a conflict of interest that warrants exclusion from 4 developing or influencing the evaluations of carcinogenicity

(LP) in plasma associated with being close to cellular towers. **Zothansiama et al. (2017)** [233] studied 40 people living close to cellular towers (<80 meters) with people living further away (>300 meters) in a different population in India and measured RF power-density in the bedrooms of all of the participants. They saw the same changes in SOD, CAT and LP. In addition, increasing power-density measurements were associated with increased micronuclei (MN) in peripheral blood lymphocytes. **Khalil et al. (2014)** [234] and **Abu et al. (2015)** [235] reported on the same set of 12 individuals whose saliva was sampled before and after 15 and 30 minutes of use of a specific cellular phone (1800 MhZ Nokia with an SAR of 1.09). They saw an increase in SOD, but no change in malondialdehyde (MDA) or 8-hydroxydeoxyguanosine (8-OHdG, a measure of oxidative damage). **Malini (2017)** [236] compared usage in 47 males in India in groupings of 1-5 hours/day (20 men), 5-10 hours/day (22 men) and >10 hours/day (5 men) and saw no changes in ROS, ROS scavengers or DNA damage in semen.

6.2.3.2 Mouse

In the discussion that follows, unless otherwise mentioned, SAR values used in the studies are generally less than 1 W/kg either whole body or tissue specific. Details can be found in Supplemental Table 1.

6.2.3.2.1 BALB/c Mice

Khalil et al. (2011) [237] saw no changes in oxidative stress in brain, spleen or serum in BALB/c mice exposed for 30 days to 900 MHz RF at 1 W/kg SAR. **Bahreyni et al. (2018)** [238] saw changes in reactive oxygen species (ROS) and/or ROS-scavenging enzymes in heart, liver, kidney, cerebellum and hippocampus in the dams and heart, liver, kidney, and cerebellum of their offspring from pregnant female BALB/c mice exposed for 20 days to joint 900/1800 MHz RF for which the SAR was not provided.

6.2.3.2.2 Parkes Mice

Shahin et al. (2013) [239] saw the expected changes in ROS and ROS-scavenging enzymes (SOD, CAT, GST) in the liver, kidney ovaries and blood of pregnant Parkes mice exposed for 45 days to 0.023 W/kg of 2450 MHz RF and saw associated DNA damage in the brains from the same exposure.

6.2.3.2.3 Swiss Mice

Shahin et al. (2014) [240] saw an increase in ROS and associated changes in ROS scavengers in the hypothalamus, liver, kidney and testis of male Swiss mice exposed for 30 days to 0.018 W/kg 2450 MHz RF and saw significant tissue toxicity in the testis. **Shahin et al. (2017)** [241] also saw an increase in ROS and associated changes in ROS scavengers in the hypothalamus, uterus and ovaries of female Swiss mice exposed for 100 days to an unknown SAR from a 1800 MHz cellular phone. They also saw significant tissue changes in the uterus and a modification of reproductive hormones. **Shahin et al. (2018)** [242] saw changes in stress-related hormones and associated markers in the hippocampus and blood of male Swiss mice exposed for 15, 30 or 60 days to 0.0146 W/kg 2450 MHz RF. These stress changes, probably associated with induced nitrous oxide, led to reductions in learning and spatial memory in these mice. **Shahin et al. (2018)** [243] saw an increase in ROS and associated changes in ROS scavengers , increased apoptosis, and tissue toxicity in the testis of male Swiss mice exposed for 120 days to 0.05 W/kg 1800 MHz (using a mobile phone). **Pandey et al. (2017)** [244] saw mitochondrial damage, other cellular damage and DNA damage in spermatocytes of male Swiss mice exposed for 35 days to 0.0045-0.0056 W/kg 900 MHz RF; they attributed these changes to oxidative stress.

Esmekaya et al. (2016) [245] exposed Swiss mice with chemically-induced epileptic seizures (induced by pentylenetetrazole) for 15 or 30 minutes to a 900 MHz cellular phone with a head SAR of 0.301 W/kg and saw changes in ROS and ROS scavengers in the brain.

[illegible]

Zong et al. (2016) exposed male ICR mice for 7 days to 0.05 W/kg 900 MHz RF and saw no changes in ROS in liver, lung and blood. **Zong et al. (2015)** [246] exposed male mice to 0.05 W/kg 900 MHz RF for 4 hours/day for 7 days and saw no significant changes in ROS, ROS scavengers or DNA damage in liver, lung and blood.

[illegible]

Jeong et al. (2018) exposed 14 month old female C57BL/6 mice for 8 months to 5 W/kg 1950 MHz RF and saw no changes in ROS, apoptosis or DNA damage in the brain and no change in locomotor activity.

[illegible]

The best-studied strain of mouse is the Swiss-albino mouse and all studies using these mice demonstrated indications of oxidative stress induced by RF in multiple studies in the brain and testis and in single studies to the uterus, ovaries, liver and kidney at multiple frequencies and very low SARs. Three of the seven studies in Swiss mice used cellular phone exposure systems. In BALB/c mice, there is one negative study in brain, serum and spleen at 1 W/kg SAR, 900 MHz and 1 positive study in brain, heart, liver and kidney at 900/1800 MHz but an unknown SAR. One study in Parkes mice shows clear oxidative stress in liver, kidney and ovaries, DNA damage in the brain and changes in blood chemistry for a low SAR at 2450 MHz. In ICR mice, there is one study showing no changes in oxidative stress in liver, lung and blood at a low SAR at 900 MHz. Finally, in C57BL/6 mice, there is one study with no indication of oxidative stress in the brain at a much higher SAR at 1950 MHz.

In summary, RF can cause oxidative stress in the brain, testis, liver, kidney, uterus, heart and ovaries of Swiss-albino mice and the liver, kidney, ovaries and brain of ICR mice. There is insufficient data to support a causal linkage between RF exposure and oxidative stress in other strains of mice

[illegible]

In the discussion that follows, unless otherwise mentioned, SAR values used in the studies are generally less than 1 W/kg either whole body or tissue specific. Details can be found in Supplemental Table 1

[illegible]

There are 60 studies of RF in Wistar rats of which 35 used laboratory exposure systems and 23 used cellular phones. These can be further divided by frequency and by organ to provide a summarized view of the findings. Fifteen (15) studies with laboratory exposure systems used 900-915 MHz RF, 1 used 1500 MHz, 11 used 1800 MHz, 4 used 2100 MHz, 18 used 2450 MHz, 1 used 2600 MHz and 1 used 2856 MHz (NOTE, this adds up to more than 33 studies because some studies used multiple frequencies). Seven (7) of the studies using cell phones or wifi devices used 900 MHz, 2 used cell phones with joint 900/1800 MHz, 2 used cell phones with joint 900/1800/1900 MHz, 1 used 1910.5 MHz, 3 used a 2450 MHz device, 1 used 2115 MHz and one used 2437 MHz.

All of the 8 studies in Wistar rats using laboratory systems at 900-915 MHz that evaluated oxidative stress in the brain showed changes in both ROS and ROS scavengers [247-254] with three examining and demonstrating tissue changes in the brain [250, 251, 253] (none examined DNA damage) and 2 examining and demonstrating behavioral changes [252, 253]. All 3 of the studies at only 900 MHz using a cellular phone showed changes in both ROS and ROS scavengers [255-257] with one examining and demonstrating tissue changes in the brain [256] but no significant change in DNA damage. One study at 1500 MHz showed decreases in SOD in the brain, changes in learning and spatial memory and brain tissue toxicity [258].

All of the 5 studies in Wistar rats using laboratory systems at 1800 MHz that evaluated oxidative stress in the brain showed changes in ROS and/or ROS scavengers [249-251, 259, 260] with three examining and demonstrating tissue changes in the brain [250, 251, 260] (none examined DNA damage). The one study at 900/1800 MHz using a cellular phone showed changes only in catalase activity with no other changes in either ROS or ROS scavengers [261] although they did see changes in animal behavior. Two studies in Wistar rats using laboratory systems at 2450 MHz that evaluated oxidative stress in the brain showed changes in ROS but not ROS scavengers [262, 263], one saw both change [254], one saw both change with brain toxicity [251], and one study showed no changes in ROS but used an unusual marker that appears to be focused entirely on nitrous oxides [264]. Two studies using 2450 MHz devices (wifi) were positive for both ROS and ROS scavengers with one showing changes in spatial memory from prenatal exposure [265] and the other not showing behavioral changes using adult exposure [266]. Studies were also clearly positive for the brain at 2100 MHz [267], 2115 MHz [268, 269] and 2856 MHz [258].

Sixteen (16) studies in Wistar rats looked at oxidative stress in the testis or sperm. Four (4) studies using laboratory-created 900 MHz saw changes in ROS and/or ROS scavengers (depending on what was measured) [270-273] and one saw changes in ROS but not ROS scavengers [274], two measured and demonstrated changes in tissue [272, 273] and one measured and demonstrated damage to DNA [272]. The two studies using 900 MHz cellular phones saw changes in ROS and ROS scavengers [275, 276] with one measuring and demonstrating both tissue damage and DNA damage [275]. One study with laboratory-generated 1800 MHz RF had no statistically significant change in ROS, but did see changes in ROS scavengers and apoptosis [277] and one study saw both ROS and ROS scavengers changed [271]. The one study using a 900/1800 MHz cellular phone saw changes in ROS and ROS scavengers and tissue toxicity [278]. One study with a combined 900//1800/1900 MHz cellular phone examined only ROS scavengers and saw changes and tissue toxicity [279]. The one study with a laboratory generated 2450 MHz signal saw changes in both ROS and ROS scavengers [271]. Single studies at 1950 MHz [280], 2100 MHz [281] and 2437 MHz

[282] saw changes to both ROS and ROS scavengers with two examining and demonstrating tissue toxicity [280, 282].

Heart tissue was examined in 4 studies. One, using 2450 MHz saw changes in ROS and ROS scavengers, tissue toxicity and apoptosis [283]. Another, also at 2450 MHz, saw changes in ROS and ROS scavengers, but not for all markers examined [284], and another at 2450 MHz saw changes in ROS but not ROS scavengers. The final study used laboratory generated 900 MHz and saw changes in ROS and ROS scavengers [270].

Liver tissue was examined in 7 studies in Wistar rats. Two studies using laboratory-created 900 MHZ [249, 270] and one using a 900 MHz cellular phone [285] saw changes in ROS and ROS scavengers. One study at 1800 MHz saw changes in ROS and ROS scavengers [249] while another showed no significant changes [286]. The one study using laboratory-created 2450 MHz showed an increase in ROS and tissue toxicity but did not look for changes in ROS scavengers [287] and another using laboratory-created 2600 MHz saw no significant change in ROS or ROS scavengers but did see tissue changes [288]. The one study using 1910.5 MHz saw an increase in ROS (scavengers not evaluated) and increased DNA damage.

Kidney tissue was examined in 3 studies; two were positive for changes in both ROS and ROS scavengers, one using 2450 MHz [289] and the other examining the frequencies of 900, 1800 and 2450 MHz [271]. One study showed no change in ROS (ROS scavengers not examined) using 1800 MHz [286].

Three studies evaluated the effect of RF in the eye epithelium of Wistar rats and all were effectively negative [290-292].

One study using laboratory-generated 2450 MHz saw increased ROS in the spleen (ROS scavengers were not examined) [287]. One study using laboratory-generated 900 MHz saw changes in ROS and ROS scavengers in the lung [270]. The Laryngotracheal mucosa was examined in one study using 2450 MHZ showing increased ROS but no significant change in ROS scavengers [293]. The ovary was examined in one study using 2450 MHZ showing increased ROS (ROS scavengers were not examined) [294]. One study using the three frequencies 900, 1800 and 2450 MHz saw changes in ROS for all three frequencies but no significant changes in ROS scavengers [295] in uterus and blood. A single study using 900 MHz saw changes in ROS and ROS scavengers in lymphoid tissues and blood [296]. A cell phone at 900 MHz only was used for one study and at a combined 900/1800/1900 MHz phone for one other study. Finally, one study used a combined 848.5/1950 MHz signal that was laboratory generated.

6.2.3.3.2 Sprague-Dawley Rats

There are 37 studies in Sprague-Dawley (SD) rats. Laboratory-generated RF at 900 MHz was used in 21 studies, 1800 MHz in 4 studies, 2100 MHz in 2 studies, and 2450 MHz in 5 studies [297-301].

Five studies evaluated oxidative stress in the brain using a laboratory-generated 900 MHz signal, and all of them demonstrated some degree of stress. Three studies demonstrated changes in both ROS and ROS scavengers [297, 299, 301] with 2 also demonstrating tissue changes in the brain [299, 301]. One study [298] saw no significant change in ROS but changes in ROS scavengers and tissue toxicity and one only examined a single ROS scavenger (significantly decreased) and saw changes in learning, spatial memory and the blood-brain barrier. One study [302] using laboratory-generated 900, 1800 and 2100 MHZ saw changes in ROS and ROS scavengers at all three frequencies in the brain and significant DNA damage at 2100 MHz. One last study [303] using laboratory-generated 2450 MHz RF saw changes in gene expression and protein levels in the brain linked to oxidative stress and tissue response.

Three studies [304-306] examined oxidative stress in the testis or sperm using a laboratory-generated 900 MHz signal with all showing changes to ROS and ROS scavengers and 2 examining and demonstrating tissue changes and increased apoptosis [304, 306]. One study using a 900 MHz cellular phone demonstrated changes in ROS, ROS scavengers, tissue toxicity and apoptosis [307], whereas another using a 900/1800/1900 MHz cellular phone failed to demonstrate any significant changes in ROS, ROS scavengers or tissue toxicity [308]. A single study using a laboratory-generated 2450 MHZ signal with a moderate SAR (3.21 W/kg) demonstrated increases in ROS, decreases in ROS scavengers and increased tissue toxicity [309]. The final study evaluating oxidative stress in the testis used a combined 848.8/1950 MHz signal and a moderate SAR (4 W/kg) and failed to see any changes in ROS or tissue toxicity (ROS scavengers were not evaluated) [310].

Four studies examined oxidative stress in the kidney using laboratory-generated 900 MHz signals, 2 saw changes in ROS, ROS scavengers and tissue toxicity [299, 311], one saw increased ROS, tissue toxicity and apoptosis (ROS scavengers not examined) [312], and one saw no significant changes in ROS or ROS scavengers although they did see kidney toxicity [313]. One other study in the kidney used 2100 MHz and demonstrated changes in ROS, ROS scavengers, tissue toxicity and apoptosis [314]. **Turedi et al. (2017)** [312] also examined the bladder and saw clear changes in oxidative stress.

Four studies examined oxidative stress in the liver using laboratory-generated 900 MHz signals, 2 saw changes in ROS, ROS scavengers and tissue toxicity [299, 315], one saw increased ROS and decreased ROS scavengers (tissue toxicity not examined) [316], and one saw no significant changes in ROS, some changes in ROS scavengers and kidney toxicity [317]. One other study in the liver used 1800 MHz demonstrated changes in ROS, ROS scavengers and tissue toxicity [318].

Two studies looked at ovaries, one using 900 MHZ [319] and one using 2450 MHZ [320], saw changes in ROS and tissue toxicity but no changes in ROS scavengers. **Saygin et al. (2018)** [320] also looked at uterus and fallopian tubes and saw no significant changes in any oxidative stress markers.

Two studies in SD rats examined oxidative stress in the heart using laboratory-generated 900 MHz signals. One study, using in-utero exposure, saw clear increases in ROS and decreases in ROS scavengers with tissue toxicity and apoptosis [321]. The other study, using young rats, saw increased ROS, increased apoptosis, but no changes in ROS scavengers or in tissue toxicity [322].

Two studies in SD rats examined oxidative stress in the spinal cord using laboratory-generated 900 MHz signals with almost identical protocols. Both studies saw clear increases in ROS and weak or non-significant changes in ROS scavengers with tissue toxicity and apoptosis[323, 324]. One study using laboratory-generated RF looked at the sciatic nerve and saw changes in ROS and ROS scavengers, apoptosis and tissue toxicity [325].

Single studies evaluated the ear (increased ROS, no other changes) [326], pancreas (ROS, ROS scavengers and tissue changes) [327], spleen and thymus (ROS, ROS scavengers and tissue changes) [328] and eyes (ROS, ROS scavengers) [305].

6.2.3.3.3 *Other* Rat Strains

Three studies examined RF oxidative stress in Fischer rats. One study used laboratory-generated signals at 900, 1800 and 2450 MHz and saw changes in ROS and ROS scavengers, DNA damage and inflammation in the brain [329]. A second study evaluated blood using a 900 MHz signal and saw changes in ROS and ROS scavengers in blood and changes in learning and spatial memory [330]. The final study used 900 and 1800 MHz signals and recorded changes in ROS, ROS scavengers, and tissue changes in the brain with associated learning and spatial memory deficits [331].

Two studies listed their rats as albino; these could have been Wistar rats. One study evaluated serum exposed to a 900 MHz laboratory-derived field and saw a decrease in ROS scavengers (ROS was not evaluated) [332]. The second examined parotid glands in rats exposed to a 900 MHz cellular phone and observed an increase in ROS and a decrease in ROS scavengers with associated tissue changes [333].

The only study in Long-Evans rats used a laboratory-generated 900 MHz signal and saw changes in stress hormones in the brain but no significant changes in learning or spatial memory [334].

One study appears to have used locally-caught wild rats, exposed them to a 2100 MHz mobile phone and demonstrated an increase in creatinine kinase-MB (indicator of oxidative stress in the heart) and a decrease in cardiomyocytes [335].

Four studies failed to identify the strain of rat [336-339].

6.2.3.3.4 Summary in Rats

The best-studied strains of rat are the Wistar and SD rats and these show clear indications of oxidative stress induced by RF in multiple studies in the brain and testis and some indication of oxidative stress in the heart. The SD rats also seem to have consistent evidence of oxidative stress in the liver and kidney. Other findings in female reproductive organs, spinal cord, eye and other tissues are shown in 1 or 2 studies each. In other strains of rat, the most prominent findings are in the brain where there is generally increased oxidative stress. Most of these findings are at SARs below 1 W/kg and seem to occur regardless of the frequency used.

In summary, RF can cause oxidative stress in the brain, testis, and heart of SD and Wistar rats and the liver and kidney of SD rats. Brain appears to be a target for oxidative stress in Fischer rats. There is insufficient data to support a causal linkage between RF exposure and oxidative stress in other strains of rat.

6.2.3.4 Other Laboratory Species

Three studies looked at the effects of RF on oxidative stress in New Zealand White rabbits. **Guler et al. (2016)** [340] used laboratory-generated 1800 MHz signals and saw increases in brain ROS (ROS scavengers were not examined) in male rabbits exposed both in-utero and after birth but not in females. **Guler et al. (2012)** [341] used the same laboratory set up and study design and saw changes in liver ROS and ROS scavengers and an increase in 8-OHdG in females, but no direct DNA damage. **Ogur et al. (2013)** [342] in an earlier study used the same exposure and saw increased ROS in blood for males and females with in-utero exposure and for females (not males) with exposure 1 month after birth. This same research group had done an earlier study with a similar design and saw no significant changes in blood [343].

One study examined laboratory-generated 900 MHz signals in Guinea pigs and saw a reduction in ROS scavengers in the liver but no significant change in ROS.

There is insufficient data to support a causal linkage between RF exposure and oxidative stress in laboratory species other than rats and mice.

6.2.4 *In Vitro* Studies in Mammalian Cells

6.2.4.1 Human Cells

6.2.4.1.1 Primary Cells

In vitro studies in primary cells refer to the use of cells taken directly from humans, then exposed in a laboratory to RF where oxidative stress is evaluated. Three studies exposed human sperm to RF and evaluated oxidative stress. Using a 900 MHZ mobile phone led to changes in ROS (ROS scavengers not examined) and DNA damage [344]. Using a laboratory-generated 1950 MHz signal resulted in no significant changes in ROS [345]. Using a 2450 MHz cellular phone resulted in clear oxidative stress with changes in both ROS and ROS scavengers [346].

Three studies used peripheral blood. Monocytes showed changes in ROS, ROS scavengers and apoptosis after being exposed to a laboratory-generated 900 MHz signal [347]. In another study, monocytes, but not lymphocytes, saw an increase in ROS (ROS scavengers not evaluated) after exposure to a laboratory derived 900 MHz signal [348]. The third study, both monocytes and lymphocytes exposed to a laboratory-derived 1800 MHz signal showed changes in ROS scavengers (ROS was not directly measured) [349]. A single study used umbilical cord blood exposed using a 900 MHz cellular phone resulting in an increase in ROS [350].

A single study used astrocytes from human brains exposed to 918 MHz RF and saw a decrease in ROS (ROS scavengers not examined) [351] (Note, this study was aimed at RF as a therapy for Alzheimer's).

Human stem cells exposed to 900, 1950 or 2535 MHz RF saw no significant changes in ROS apoptosis or DNA damage except for DNA damage that was shown at 900 MHz [352].

One study used primary cells from human skin, umbilical veins and amniotic fluid and saw no increase in ROS, saw binucleated nuclei in skin but no DNA damage via comet assay [353]

The final study of human primary cells used thyroid gland cells exposed to 900 or 895 MHz RF and saw no significant increase in oxidative stress [354].

Three (3) of these studies used SAR above 1 W/kg.

[illegible]

Two studies using the same basic design of 1 hour exposure to 2450 MHz RF saw a significant change in ROS and ROS scavengers [355, 356]. The only other study used a 940 MHz signal and also resulted in significant change in ROS and ROS scavengers [357].

[illegible]

Two studies, one at 900 MHz [358] and the other at 2450 MHz [359] both demonstrated increases in ROS and changes in ROS scavengers. The 900 MHz study [358] also saw damage to mitochondrial DNA. Finally, HL-60 cells exposed to 900, 1950 or 2535 MHz RF saw no significant changes in ROS or apoptosis [352]. Only 1 study used SARs above 1 W/kg.

[illegible]

Two studies, one with 935 MHz [360] and the other with 1800 MHz [361], saw no changes in oxidative stress. Two studies, one with 837 and 1950 MHz [362] and the other with 1800 MHz wifi device [363], saw changes in ROS only (changes in ROS scavengers were not evaluated). Finally, two studies, one with 935 MHz [364] and the other with 1800 MHz [365], saw changes in both ROS and ROS scavengers. Five of these studies used SARs greater than 1 W/kg.

[illegible]

Studies in AC5 cells (adipose tissue), Huh7 cells (liver), and U87 cells (glioma) all studied only ROS and demonstrated a significant increase in ROS [362, 366]. Studies in U-87 MG cells (glioma), MCF-7 cells (breast cancer), MDA-MB-231 cells (breast cancer) and HLE B3 cells (lens epithelium) studied a full spectrum of ROS and ROS scavengers and saw significant indications of oxidative stress [361, 362, 367-369]. A single study in MCF10A cells (breast) so no increase in ROS or ROS scavengers[370].

[illegible]

[illegible]

One study in Leydig cells saw changes in ROS and ROS scavengers after exposure to RF [371]. Another study of preantral follicles (ovaries) also saw changes in ROS and ROS scavengers after exposure to RF [372]. A study of spermatocytes saw an increase in ROS associated with an increase in DNA damage [373].

[illegible]

Three studies used NIH/3T3 cells. All three saw increases in ROS but did not study ROS scavengers [362, 374, 375] with two also showing an increase in apoptosis [374, 375].

[illegible]

Four studies evaluated the effects of RF on mouse derived spermatocyte cell line GC1 and/or GC2. All four saw increases in ROS [373, 376-378], 2 of these showed increases in DNA damage [376, 377], 2 saw increases in 8-OhdG [373, 377] and one saw an increase in apoptosis [378].

[illegible]

Two studies in N9 cells saw significant changes in ROS and ROS scavengers [364, 379] and one study demonstrated an increase in NO [380].

[illegible] Other Neural Cell Lines

One study with Neuro-2A cells (neuroblastoma) saw an increase in ROS (did not study ROS scavengers), but no significant change in DNA damage [381]. Two studies in the same laboratory evaluated RF and HT22 cells (hippocampus), neither study evaluated ROS scavengers, one saw a significant increase in ROS and a change in cell cycle [382] while the other with lower SAR values and two frequencies combined saw no significant change in ROS [383]. One study in RAW 264.7 cells (macrophage) saw an increase in ROS but did not study ROS scavengers [384]. Finally, one study using TM3 cells (leydig) saw changes in ROS and ROS scavengers but no change in apoptosis [385].

[illegible]

Two studies used rat primary cells from the brain. One saw a decrease in ROS (scavengers not evaluated) in astrocytes when exposed to 918 MHz RF and challenged with hydrogen peroxide [351]. One study of rat neonatal spinal ganglia and neurons exposed to 1800 MHz RF saw an increase in ROS but no DNA damage [386].

One additional study used PC12 cells (rat derived pheochromocytoma cell line) exposed simultaneously to 837 MHz and 1950 MHz RF saw significant increased ROS at 12 hours but not at other times in a 24 hour window.

[illegible] Cells Derived from Hamsters

Two studies exposed V79 cells (hamster lung cells) to 1800 MHz with one seeing increased ROS (nothing else studied) [387] and the other showing increased ROS and ROS scavenger activity [388]. A final study using CHO cells (ovaries) exposed to 900 MHz saw increased ROS (scavengers not evaluated) that remained 12 hours after exposure stopped [389].

8.2.5 Summary for Oxidative Stress

Most of the in-vivo and in-vitro studies of oxidative stress saw significant increases in ROS. Most of the studies that evaluated ROS scavengers saw significant changes in these markers that is associated with oxidative stress, the tissue or cells. Nineteen (19) in-vivo studies, 18 done in rats or mice and one in rabbits, evaluated oxidative stress as well as DNA damage, about half with SARs below 1 and a mix of exposure durations and almost all of them showed an increase in DNA damage.

Although reactive oxygen species can potentially cause damage to cellular function and structure and thereby impair its functionality, their presence and production cannot be immediately considered as harmful because changes in the levels of ROS and ROS scavengers is a normal part of cellular metabolism and physiology. Thus, many of the studies in this section simply demonstrate a change and not necessarily harm. However, tissue toxicity, increased DNA damage and changes in apoptosis do indicate that the changes in ROS are sufficient to impair cellular function and damage cellular components.

Many of the studies presented in this section did address these issues. With respect to cancer, of greatest concern would be damage to DNA. Twelve (12) of these in-vivo studies showed an increase in DNA damage associated with oxidative stress [239, 244, 256, 268, 272, 275, 302, 329, 338, 390-392], seven (7) did not see a significant change in DNA damage [236, 246, 256, 337, 341, 393, 394] and one saw a significant decrease in DNA damage after 15 days of exposure and an increase after 30 days of exposure [336]. Eight (8) in-vitro studies evaluated some aspect of oxidative stress as well as DNA damage, all of them with rather short exposure periods and most with SARs greater than 1. Five (5) of these studies demonstrated increases in DNA damage [344, 346, 352, 376, 377] and three (3) saw no significant increase in DNA damage [353, 381, 386].

There is sufficient evidence in the literature to conclude that oxidative stress is a possible mechanism by which RF causes cancer in humans.

6.3 Genotoxicity

6.3.1 Introduction

Genotoxicity refers to the ability of an agent (chemical or otherwise) to damage the genetic material within a cell, thus increasing the risks for a mutation. Genotoxic agents interact with the genetic material, including DNA sequence and structure, to damage cells. DNA damage can occur in several different ways, including single- and double-strand breaks, cross-links between DNA bases and proteins, formation of micronuclei and chemical additions to the DNA.

Just because a chemical can damage DNA does not mean it will cause mutations. So, while all chemicals that cause mutations are genotoxic, all genotoxic chemicals are not necessarily mutagens. Does that mean that the genotoxicity of a chemical can be ignored if all assays used for identifying mutations in cells following exposure to a chemical are negative? The answer to that question is no and is tied to the limitations in tests for mutagenicity (the ability of a chemical to cause mutations in a cell). It is unusual to see an evaluation of the sequence of the entire genome before exposure with the same sequence after exposure to determine if the genome has been altered (mutation). There are assays that can evaluate a critical set of genes that have previously been associated with cancer outcomes (e.g. cancer oncogenes), but these are seldom applied. In general, mutagenicity tests are limited in the numbers of genes they actually screen and the manner in which these screens work.

Because screening for mutagenicity is limited in scope, any genetic damage caused by chemicals should raise concerns because of the possibility of a mutation arising from that genetic damage. In what follows, the scientific findings available for evaluating the genotoxic potential of RF will be divided into four separate sources of data based on the biological source of that data: (1) data from exposed humans, (2) data from exposed human cells in a laboratory setting, (3) data from exposed mammals (non-human), and (4) data from exposed cells of mammals (non-human) in the laboratory. These four areas are based upon the priorities one would apply to the data in terms of impacts. Seeing genotoxicity in humans is more important than seeing genotoxicity in other mammals. In addition, seeing genotoxicity in whole, living organisms (*in vivo*) carries greater weight than seeing responses in cells in the laboratory (*in vitro*). Basically, the closer the findings are to real, living human beings, the more weight they should be given.

6.3.2 International Agency for Research on Cancer (IARC)

The IARC reviewed the potential for carcinogenicity from RF in 2011 [35]. They evaluated the scientific literature prior to 2011 and concluded "*there was weak evidence that RF radiation is genotoxic, and no evidence for the mutagenicity of RF radiation .*" This conclusion was driven by methodological shortcomings in the studies, lack of a sham-controlled group in some studies, use of mobile phones for exposures, poor dosimetry and contradictory results. Having looked over the IARC review, I agree with their assessment of these data and will not discuss any studies prior to 2010.

6.3.3 *In Vivo* Studies in Mammals

6.3.3.1 Humans

Several studies have addressed the presence of DNA damage directly in humans using the duration or frequency of cellular phone usage and comparing easily obtained human tissues (e.g. buccal swaps, sperm/semen, peripheral blood). **Vanishree et al. (2018)** [395] examined buccal swabs from 86 18-30 year-old cell phone users (46 M, 40 F) for micronuclei (MN). They compared low mobile phone users (<5 years and <4-5 hr/week) to high mobile phone users (>5 years and more than 10 hr/week) and saw an increase in MN in the high exposure group. They also saw an increase in MN on the side of the mouth where the mobile phone is used (ipsilateral) and in those who failed to use a headphone. **de Oliviera et al. (2017)** [396] examined buccal swabs from 30 male and 30 female 20-28 year-old cell phone users for MN. They saw no increase in MN by duration of use, frequency of use or ipsilateral vs. contralateral exposure. The categories for duration of use were unbalanced and they found no relationship with smoking (which is a known risk factor). Gulati et al. (2016) [397] examined buccal swabs from 116 people (68 M, 48F) residing near mobile towers (not defined but Table 1 suggests ≤400 meters) to 106 people living >800 meters from mobile towers (age range not provided). They found an increase in MN in buccal cells associated with distance to the cell tower and duration of use but saw no association with tobacco use. **Bannerjee et al. (2016)** [398] examined buccal swabs from 300 male 20-30 year-old cell phone users for MN. They compared low mobile phone users (<5 years and <3 hr/week) to high mobile phone users (>5 years and more than 10 hr/week). They saw an increase in MN in the high exposure group, an increase in MN on the ipsilateral side and in those who failed to use a headphone; they did not adjust for other risk factors. **Daroit et al. (2015)** [399] examined oral mucosa swabs from 3 different regions of the mouth of 60 people (24 M, 36 F) aged 19-33 years for MN and other genetic damage markers (broken eggs, binucleated cells, karyorrhexis). They saw increased MN on the whole mucosa and lower lip and increased binucleated cells (BN) on the border of the tongue for those using cellular phones for >60 minutes per week and increased broken eggs (BE) on the border of the tongue for those using cell phones for >8 years; all other comparisons were non-significant and no other risk factors were evaluated. **Sousa et al. (2014)** [400] examined ipsilateral-only oral mucosa cells in three groups (> 5 hr/week, >1 and ≤5 hr/week, ≤ 1 hr/week) of 15 individuals (sexes not specified) for the presence of MN, BE and degenerative nuclear anomalies (DN). They saw no changes in MN or DN but did see an increase in BE as a function of duration of usage per week (no other risk factors were examined). **Ros-Lior et al. (2012)** [401] examined buccal swabs from 50 (16 M, 34 F)

Caucasian 20-40 year-old cell phone users for MN. They compared short-term mobile phone users (<10 years) to long-term mobile phone users (>10 years). They saw no increase in MN, BN or DN in the long-term users nor did they see any relationship to ipsilateral use; they did not adjust for other risk factors and saw no relationship with smoking.

Radwan et al. (2016) [402] studied the effect of stress on sperm DNA damage in 286 males. They saw no indication of an increase in DNA fragmentation in sperm as a function of years of cell phone use (≤5, >5 to ≤10, > 10 years). In an earlier study from the same group using 344 men (286 in the 2016 study are included here) **Jurewicz et al. (2014)** [403] had a similar finding.

Gulati et al. (2016) [397] also examined peripheral blood lymphocytes (PBL) from 116 people (68 M, 48F) residing near mobile towers (not defined but Table 1 suggests ≤400 meters) to 106 people living >800 meters from mobile towers (age range not provided). They found an increase in tail moment (TM) (comet assay) associated with distance to the cell tower and duration of use but saw no association with tobacco use. **Gandhi et al. (2015)** [404] used the comet assay to evaluate DNA damage in PBL from 63 (38 M, 25 F) people with residences near (50-300 meters) a mobile phone tower and 28 controls (15 M, 13 F) with no nearby towers at home or work. All evaluations of DNA damage regarding distance to towers as well as mobile phone usage were significantly higher in the high exposure categories.

Cam and Seyhan (2012) [405] examined the hair roots of 8 individuals (6 women, 2 men) before and after 15 minutes exposure to a cellular phone and then 2 weeks later, before and after exposure for 30 minutes to a cellular phone. The comet assay showed a clear increase in single strand breaks after both 15 and 30 minutes of use with 30 minutes of use showing the greatest amount of damage.

6.3.3.2 Mice

In the NTP Study [166] using B6C3F1 mice, after 14 weeks of exposure, **Smith-Roe et al (2020)** [168] evaluated genotoxicity in several tissues of mice included in these studies for this purpose using the alkaline comet assay (three brain regions, liver, peripheral blood) and the micronucleus assay (peripheral blood). Significant increases in DNA damage were seen in the frontal cortex of male mice (DCMA and GSM) and leukocytes of female mice (CDMA only).

Jiang et al. (2013) [406] exposed groups of 10 male ICR mice to 900 MHz RF, SAR 0.548 W/kg, for 4 hr/day for 7 days and examined for MN in erythrocytes and bone marrow. They saw no significant changes in MN in either tissue, however, they did not use a sham control group. **Jiang et al. (2012)** [407] exposed groups of 5 male ICR mice to 900 MHz RF, SAR 0.548 W/kg, for 4 hr/day for 1,3,5,7 or 14 days and examined for general DNA damage (comet assay) in leukocytes. They saw no significant changes for any duration of exposure, however, they also did not use a sham control.

Chaturvedi et al. (2011) [408] exposed groups of 5 male Parks mice to 2450 MHz, SAR 0.0356 W/kg RF for 2 hr/day for 5 days. They saw an increase in tail moment, tail DNA and tail length in brain tissue using the comet assay.

6.3.3.3 Rats

In the NTP Study [166] using Sprague-Dawley rats, after 14 weeks of exposure, **Smith-Roe et al (2020)** [168] evaluated genotoxicity in several tissues of rats included in these studies for this purpose using the alkaline comet assay (three brain regions, liver, peripheral blood) and the micronucleus assay (peripheral blood). Significant increases in DNA damage were seen in the hippocampus of male rats (CDMA-only). **Usikalu et al. (2013)** [409] exposed groups of 2 male and 2 female Sprague-Dawley rats to 2450 MHz RF at SARs of 0, and 2.39 W/kg for 10 minutes and evaluated the induction of DNA damage by comet assay in the ovaries (F) and testis (M). Both tissues showed a significant increase in DNA damage as a function of exposure.

Akdag et al. (2016) [410] exposed groups of 8 male Wistar rats to 2450 MHz RF for 24 hr/day for 12 months at SARs of 0 or $1.41 \bullet 10^{-4}$ W/kg. Using the comet assay, they examined DNA damage in the brain, liver, kidney and testis and only saw increased DNA damage in the testis. **Gurburz et al. (2014)** [411] exposed groups of 6 male Wistar rats to 1800 MHz, SAR 0.23 or 2100 MHz, SAR 0.23 for 1 or 2 months. They examined only the urinary bladder and saw no increases in MN. **Atli et al. (2013)** [412] exposed groups of 2-week old and 10-week old Wistar rats (sex not provided) to 900 MHz RF, SAR 0.76 (2-week old) or 0.37 (10-week old) W/kg for 2 hr/day, 45 days with and without a recovery period of 15 days. Significant DNA damage (chromosomal aberrations, MN, and polychromatic erythrocytes) in bone marrow was seen for all of the experimental groups. Using the same experimental design with 1800 MHz RF, SAR 0.37 (2-week) and 0.49 (10-week), **Sekeroglu et al. (2012)** [413] saw the same significant DNA damage. **Trosic et al. (2011)** [414] exposed groups of 9 male Wistar rats to 915 MHz RF, SAR 0.6 W/kg, for 1 hr/day, 7 d/week, 2 weeks. They saw increases in DNA damage (comet assay) in liver and kidney, but not in brain.

Gouda et al. (2013) [415] exposed groups of 15 male albino (probably Wistar) rats to 1800 MHz RF, SAR 0.3 W/kg, from a cellular phone for 2 h/day either continuous or discontinuous (30 min on, 30 min off) for 2, 4 or 6 weeks. Using genomic DNA from the liver, they saw a significant increase in mutations to two genes (TP53 and BRCA1) after 6 weeks of exposure in the continuous group and a significant increase in DNA fragmentation at all durations for continuous exposure.

In a series of 3 studies, **Deshmukh et al. (2013, 2015, 2016)** exposed groups of 6 male Fischer rats to 900 MHz RF, SAR $5.95 \bullet 10^{-4}$ W/kg, 1800 MHz RF, $5.83 \bullet 10^{-4}$ W/kg, or 2450 MHz RF, $6.67 \bullet 10^{-4}$ W/kg, for 2 h/day, 5 d/week, 30 days [416], 90 days [417] or 180 days [418]. Increases in DNA damage in the brain in the 30-day study and hippocampus in the other two studies were seen using the comet assay.

6.3.3.4 Summary for DNA Damage In-Vivo

DNA damage was seen from exposure to RF in humans (5 studies of oral mucosa cells, 2 in PBL and 1 in hair follicles), mice (2 studies) and in rats (8 studies). Four studies in humans (2 oral mucosa cells, 2 sperm cells), 2 studies in mice which failed to use sham controls, and 1 study in rats saw no increases in DNA damage. In laboratory animals, 2 studies at 900 MHz saw no DNA damage while 6 were positive, one study using 1800 and 2100 MHz RF was negative while 5 using 1800 MHz were positive and all 6 studies using 2450 MHz were positive. In humans, most studies failed to control for confounders and failed to find an association with smoking that should have been apparent. The strongest study, using hair follicles, used the individuals as their own control and this study was positive.

6.3.4 *In Vitro* Studies in Mammalian Cells

6.3.4.1 Humans

6.3.4.1.1 Primary Cells

Five studies exposed human PBL to RF. One study using laboratory-generated 900 MHz for 30 minutes with 60 minutes recovery saw no change in DNA repair [419]. One multi-laboratory study using laboratory-generated 1800 MHz RF for 28 hours saw no changes in MN, sister-chromatid exchange, chromosomal aberrations or comet assay tail moment [420]. Two studies with laboratory-generated 1950 MHz RF and 20 or 24-hr exposure with a 28-hr recovery saw no changes in micronuclei [421, 422]. One study with laboratory-generated 2450 MHz RF for 72 hr and a high SAR (10.9 W/kg) saw no change in MN or binucleated DNA [423].

Both studies using semen/sperm, one using an 850 MHz phone for 60 minutes and the other using a 900/1800 MHz phone for 1 to 5 hours saw an increased DNA fragmentation index.

The final human primary cell study using amniotic cells exposed to 900 MHz RF for 24 hours at 4 different SAR values and saw no change in aneuploidy in chromosomes 1 and 17.

6.3.4.1.2 Human Cell Lines

One study using SH-SY5Y neuroblastoma cells exposed to laboratory-generated 1950 MHz RF for 20 hours saw no change in tail behavior using the comet assay [424]. In contrast, a second study using the same cell line and exposure for 16 hours saw a non-significant increased tail length in the comet assay for not only SH-SY5Y cells, but also U87, U251 and U373 glioma cells and NCH421K glioblastoma cells [425]. They also observed an increase in DNA repair but no change in double strand breaks. Another study using A172 and U251 glioblastoma cells and SH-SY5Y neuroblastoma cells using 1800 MHz for 1, 6 or 24 hours saw no increase in DNA repair [426].

Two studies used HepG2 liver cells, one at 1950 MHz for 16 hours exposure saw no changes [425] while the other using 900 or 1800 MHz RF for 1-4 hours saw morphological changes in DNA at 4 hours [427].

One study used HMy2.CIR lymphoblastoma cells exposed to laboratory-generated 1800 MHz RF for 24 hours and observed changes in DNA repair proteins [428].

A study in HL-60 leukemia cells exposed to laboratory-generated 1800 MHz RF for 24 hours saw no changes in MN or DNA damage via the comet assay [429].

One study in HaCat skin cells exposed to 900 MHz RF for 30 minutes with a 4 or 24 hour recovery saw no change in MN [430].

Two studies in human/hamster AL hybrid ovary cells exposed to 900 MHz RF for 30 minutes saw different responses; one saw aberrant spindles [431] and the other saw no changes in MN but waited at least 4 hours after exposure before evaluation [430].

Mouse

Mouse Primary Cells

Three studies from the same laboratory exposed bone marrow cells extracted from bone marrow stromal cells from male Kumming mice and exposed them to 900 MHz RF. In the first study, the cells were exposed for 3 hours/day for 5 days and poly(ADP-ribose) polymerase-1 mRNA expression (*PARP-1*) was shown to be significantly elevated for 10 hours after the final exposure (this is an indication of breaks in strands of DNA) [432]. The second study exposed the cells for 4 hr/day for 5 days, allowed the cells to recover for 4 hours and then, after measuring DNA damage (comet assay, γ-H2AX foci) saw no differences between sham controls and the RF-exposed cells [433]. The final study exposed cells for 3 hours/day for 5 days, had a three-hour recovery then measured DNA damage (comet assay, *PARP-1*) and found a large, time-dependent change in both measures but did not provide statistical p-values [434].

Another study used oocytes and spermatozoa from $B6D2F_1$ mice, exposed for 60 minutes to 1950 MHz RF, combined to allow fertilization, and then allowed 17 to 20 hours to recover. They saw no chromosomal aberrations in the resulting one-cell embryos [435].

Mouse Cell Lines

One study exposed GC-2 mouse spermatocyte cells to 1800 MHz RF for 24 hours at SARs of 1,2 and 4 W/kg and saw an increase in DNA damage (comet assay, 4 W/kg) but no change in DNA double strand breaks (g-H2AX foci) [436]. A second study exposed GC-2 cells to a 900 MHz cellular phone signal for 24 hours to four different modes of cell phone use and saw DNA damage (comet assay) for three of the modes [437].

One study exposed ataxia telangiectasia mutated (Atm-/-) and Atm+/+ mouse embryonic fibroblast cells to 1800 MHz RF for 1 to 36 hours, SAR 4 W/kg, and saw increased DNA damage (comet assay) and DNA fragmentation in the Atm-/- cells at multiple times [438].

Rat

Rat Primary Cells

One study exposed astrocytes extracted from Wistar rats to 872 MHz RF, SAR 0.6 or 6 W/kg, for 24 hours and saw no significant increase in micronuclei or DNA damage (comet assay) [439]

One study exposed femur and tibia lymphocytes extracted from Sprague-Dawley rats to 900 MHz RF for 30 minutes and saw no significant increase in DNA damage (comet assay) [440].

Rat Cell Lines

One study exposed PC12 rat pheochromocytoma cells to 1950 MHz, SAR 10 W/kg, for 24 hours and saw no significant DNA damage (comet assay) [441]

Hamster

Hamster Primary Cells

There were no studies of hamster primary cells.

6.4.3.4 Hamster Cell Line

One study using V79 hamster lung fibroblast cells exposed to laboratory-generated 2450 MHz RF for 15 minutes saw an increase in aberrant spindles and apoptosis [442]. Another study using V79 cells exposed to 1950 MHz RF for 20 hours, SAR 0.15, 0.3, 0.6 and 1.25 W/kg, saw an increase in micronuclei at the two lowest SAR values [443].

6.4.4 Conclusions for DNA Damage In Vitro

About half of the in-vitro studies showed some form of DNA damage and about half demonstrated no significant effects. There was no pattern by cell type, species, SAR or frequency. Very few of the studies used the same cell and frequency so it is difficult to give greater weight to the positive findings or the negative findings.

6.4.5 Summary for Genotoxicity

In addition to the many studies cited above and in the IARC Monograph [35], Lai (2021) [444] has compiled literature on other genetic effects (e.g. changes in gene expression) and downstream changes (e.g. cell-cycle arrest) that also point toward RF having an impact on cellular genetics and their control of cellular function.

A majority of the *in vivo* studies evaluating genotoxicity and RF, either with oxidative stress or independent of evaluating oxidative stress, showed a significant increase in DNA damage. In contrast, only about half of the *in vitro* studies of genotoxicity and RF were positive with no obvious pattern of why this might have happened.

Overall, there is sufficient evidence to suggest that genotoxicity, probably due to oxidative stress, is caused by RF and could be a mechanism by which cancer is induced by RF.

6.5 Summary for Mechanism of Carcinogenicity

There is sufficient evidence to suggest that both oxidative stress and genotoxicity are caused by exposure to RF and that these mechanisms could be the reason why RF can induce cancer in humans.

There is the possibility of publication bias in this body of literature on mechanism. Publication bias occurs when studies that are positive tend to get published whereas negative studies are either never submitted for publication or they are rejected because they are negative (rejection is less of a problem since journals are now very aware of problems with publication bias). This potential problem cannot be resolved with the data in hand. There is also a possible bias in these results based upon a small collection of laboratories providing a majority of the studies; this could also create a small amount of bias in the direction of the positive results since scientists seldom pursue negative findings but will generally continue to pursue reasons for positive findings.

7. Summary of Bradford Hill Evaluation

RF exposure probably causes gliomas and acoustic neuromas and, given the human, animal and experimental evidence, I assert that, to a reasonable degree of scientific certainty, the probability that RF exposure causes these cancers is high.

Table 22 summarizes the information for each of Hill's aspects of causality. For these data, causality is strengthened because the available epidemiological studies show a **consistent positive association** between brain tumors and RF exposure. Analyzed collectively with meta-analyses using the most reasonable combinations of studies show positive responses. And, in answer to Hill's question, the relationship between brain tumors and RF exposure has been observed by different persons, in different places, circumstances, and times. Using meningiomas as controls in some case-control studies suggests recall bias is minimal.

Causality is strengthened for these data because **the strength of the observed associations**, when evaluated simultaneously in meta-analyses, are statistically significant and the results are unlikely to be due to chance. Even though only one of the individual studies provides odds ratios that are large and precise, the meta-analyses have objectively shown that the observed association across these studies is significant and supports a positive association between brain tumors and RF.

Biological plausibility is strongly supported by the animal carcinogenicity data and the mechanistic data on genotoxicity and oxidative stress. When addressing biological plausibility, the first question generally asked is "Can you show that RF causes cancers in experimental animals?" In this case, the answer to that question is clearly yes. RF can cause tumors in experimental animals with strong findings for gliomas, heart Schwannomas and adrenal pheochromocytomas in male rats and harderian gland tumors in male mice and uterine polyps in female mice. There is also some evidence supporting liver tumors and lung tumors in male and possibly female mice. Thus, it is biologically plausible that RF can cause cancer in mammals.

The next question generally asked is "Does the mechanism by which RF causes cancer in experimental animals also work in humans?" The best understood mechanism by which agents cause cancer in both humans and animals is through damaging DNA that leads to mutations in cells that then leads to uncontrolled cellular replication and eventually cancer. It is absolutely clear from the available scientific data that RF causes oxidative stress in humans and experimental mammals. This has been amply demonstrated in humans that were exposed to RF, in human cells *in vitro*, and in experimental animal models and their cells *in vitro* and *in vivo*. One possible consequence of oxidative stress is damage to DNA and potentially mutations. RF induces DNA damage as measured in multiple ways, in humans, animals and cells, providing additional support for a biological mechanism that works in humans.

Table 22: Summary conclusions for Hill's nine aspects of epidemiological data and related science

Aspect	Conclusion	Reason
Consistency of the observed association	Strong	Multiple studies, many are positive, meta-analyses with little heterogeneity show positive findings at higher exposures, different research teams, different continents, different questionnaires, no obvious bias in case-control studies, no obvious confounding, laterality is significant
Strength of the observed association	Strong	Significant meta-analyses

Biological plausibility	Very Strong	Multiple cancers in multiple species, same tumors as humans in male rats, not due to chance, increased risk of rare tumors, convincing evidence for genotoxicity and oxidative stress
Biological gradient	Strong	Clearly seen in some case-control studies, clearly seen in the meta-analyses and met-regressions, not seen in the cohort studies, clearly seen in animal studies
Temporal relationship of the observed association	Satisfied	Exposure clearly came before cancers
Specificity of the observed association	Strong	The only cancers linked to RF exposure are gliomas and acoustic neuromas
Coherence	Strong	Cancers seen in the rats have strong similarity to human gliomas and acoustic neuromas, laterality and brain location support coherence
Evidence from human experimentation	No data	No studies are available
Analogy	No data	No studies available in the literature

In general, there is support that a **biological gradient** exists for the epidemiological data and thus support from this aspect of the Bradford-Hill evaluation. RF mRRs increased with duration of cellular phone use and with cumulative hours of exposure when studies are combined in both meta-analyses and meta-regressions. In addition, laterality is strengthened when duration of use of a cellular phone increases. The animal studies clearly demonstrate dose-response.

The proper **temporal relationship** exists with the exposure coming before the cancers.

The human evidence is **coherent**. The cancer findings in humans agree with the cancer findings in rats. Also, studies focused on the temporal lobe appear to support this area as a target for cellular phone usage. Finally, laterality, when evaluated in meta-analyses shows that tumors are more closely associated with the predominant side of the head used by people with their cellular phones.

Glioma and acoustic neuroma are not **specific** to RF exposure; however, RF exposure is specific to these two tumors. There is no **experimental evidence** in humans and I did not find any references where researchers looked for analogous exposures with similar toxicity.

Hill (1965)[34] asks "*is there any other way of explaining the set of facts before us, is there any other answer equally, or more, likely than cause and effect?*" There is no better way of explaining the scientific evidence relating RF exposure to an increase in gliomas and acoustic neuromas in humans than cause and effect.

In my opinion, RF exposure probably causes gliomas and neuromas and, given the human, animal and experimental evidence, I assert that, to a reasonable degree of scientific certainty, the probability that RF exposure causes gliomas and neuromas is high.

Appendix I: Current CV: Christopher J. Portier

CURRICULUM VITAE
Christopher J. Portier, Ph.D

Personal Data: Birth Date April 3, 1956
Birthplace Houma, Louisiana

Addresses: 4224 Midvale Ave N.
Seattle, WA
United States
Ph: +1-206-395-3308

Scheibenstrasse 15
CH-3600 Thun
Switzerland
Ph: +41-79-605-7958

Email: [illegible]

Education:

1981	**Ph.D.**	(Biostatistics), University of North Carolina, Chapel Hill
1979	**M.S**	(Biostatistics), University of North Carolina, Chapel Hill
1977	B.S.	(Mathematics), summa cum laude, Nicholls State University

Employment:

2018-present	**Scientific Advisor**, World Health Organization, Environment Program - Europe
2016–present	**Scientific Advisor on Pesticide Policies**, multiple European Non-Government Organizations
2013-present	**Consultant** to various governmental agencies (multiple countries) and law firms
2013–2014	**Senior Visiting Scientist**, International Agency for Research on Cancer, Lyon, France
2013–present	**Senior Contributing Scientist**, Environmental Defense Fund, New York City, NY
2010-2013	**Director**, National Center for Environment Health, Centers for Disease Control and Prevention, Atlanta, GA
2010–2013	**Director**, Agency for Toxic Substances and Disease Registry, Atlanta, GA
2009 – 2010	**Senior Advisor to the Director**, National Institute of Environmental Health Sciences and National Toxicology Program, Research Triangle Park, North Carolina.
2009 – 2010	**Visiting Scientist**, National Research Centre for Environmental Toxicology (EnTox), Queensland, Australia
2006 - 2009	**Associate Director**, National Institute of Environmental Health Sciences, Research Triangle Park, North Carolina.

2006 - 2009	**Director, Office of Risk Assessment Research,** National Institute of Environmental Health Sciences, Research Triangle Park, North Carolina.
1993 – 2010	**Head, Environmental Systems Biology** (originally Stochastic Modeling), Laboratory of Molecular Toxicology, National Institute of Environmental Health Sciences, Research Triangle Park, North Carolina.
2000 - 2006	**Associate Director, National Toxicology Program**, National Institute of Environmental Health Sciences, Division of Intramural Research, Research Triangle Park, North Carolina.
2000 - 2006	**Director, Environmental Toxicology Program**, National Institute of Environmental Health Sciences, Division of Intramural Research, Research Triangle Park, North Carolina.
2006-2007	**Scientific Advisor to the Director**, Public Health and the Environment Department, World Health Organization, Geneva, Switzerland (detail from NIEHS – four months)
1993 - 2005	**Chief, Laboratory of Computational Biology and Risk Analysis** (originally the Laboratory of Quantitative and Computational Biology), National Institute of Environmental Health Sciences, Division of Intramural Research, Research Triangle Park, North Carolina.
1996 - 2000	**Associate Director for Risk Assessment**, Environmental Toxicology Program National Institute of Environmental Health Sciences, Division of Intramural Research, Research Triangle Park, North Carolina.
1990 - 1993	**Head, Risk Methodology Section**, National Institute of Environmental Health Sciences, Division of Biometry and Risk Assessment, Research Triangle Park, North Carolina.
1987, 1992, 1990	**Guest Scientist**, German Cancer Research Center, Heidelberg, Germany.
1978 - 1990	**Principal Investigator**, National Institute of Environmental Health Sciences, Division of Biometry and Risk Assessment, Research Triangle Park, North Carolina.
1977	**Mathematician**, Computer Sciences Division, Oak Ridge National Laboratory, Oak Ridge, Tennessee.
1976	**Undergraduate Research Trainee**, Neutron Physics Division, Oak Ridge National Laboratory, Oak Ridge, Tennessee.

University Affiliations:

2014 – present	Visiting Professor, Department of Toxicogenomics, Maastricht University, The Netherlands
2013 – 2016	Honorary Professor, National Research Centre for Environmental Toxicology, University of Queensland, Brisbane, Australia
2011 – present	Adjunct Professor, Department of Environmental Health, Emory University, Atlanta, GA, USA
2009 – 2010	Visiting Professor, University of Queensland, Brisbane, Australia
1986 - 2007	Adjunct Professor of Biostatistics, University of North Carolina, School of Public Health, Chapel Hill, North Carolina.
1990-1992	Adjunct Professor of Statistics, University of Waterloo, Waterloo, Ontario, Canada

Honors & Awards:

- 2016 Elected Fellow, Collegium Ramazzini
- 2013 President's Dream Green Team Award for "A Human Health Perspective on Climate

Change"
- Fellow, World Innovation Foundation, 2006
- Society of Toxicology, Risk Assessment Specialty Section, Paper of the Year, 2006
- Society of Toxicology, Risk Assessment Specialty Section, Paper of the Year, 2005
- Outstanding Risk Practitioner Award, International Society for Risk Analysis, 2000.
- Elected Fellow, International Statistical Institute, 2000.
- Outstanding Performance Award, National Institute of Environmental Health Sciences, numerous dates.
- Commendation for Sustained High Quality Work Performance, National Institute of Environmental Health Sciences, numerous dates.
- Merit Award, National Institute of Health, 1998.
- Board of Publications, Best Paper Award, Society of Toxicology, 1995.
- Distinguished Achievement Award, Section on Statistics and the Environment, American Statistical Association, 1995.
- Spiegelman Award presented by the American Public Health Association to the most outstanding public health statistician under the age of 40, 1995.
- Best-applied statistics paper, Centers for Disease Control, 1993.
- Elected Fellow, American Statistical Association, 1992.
- Elected Foreign Correspondent, Russian National Academy of Natural Sciences, 1992.
- First recipient of the James E. Grizzle Distinguished Alumnus Award, The Department of Biostatistics, The University of North Carolina, 1991.

Professional Societies Membership:

Society of Toxicology, American Public Health Association, International Statistics Institute, Bioelectromagnetics Society

Editorial Activities:

- Editor in Chief - The Open Environmental Journal (2008 to 2010)
- Associate Editor – Frontiers in Predictive Toxicity (2010 to present)
- Associate Editor - Environmental Health Perspectives (1987-2006)
- Associate Editor - Risk Analysis: An International Journal (1989-2003)
- Editorial Board – Environmental and Ecological Statistics (2004-2007)
- Associate Editor – Statistics in Medicine (1998-2002)
- Associate Editor - Biometrics (1997-99)
- Editorial Board Member/Reviewer (different dates): Biometrika, Cancer Research, Communications in Statistics, Fundamental and Applied Toxicology, Journal of Applied Toxicology, Journal of the American Statistical Association, Journal of Toxicology and Environmental Health, Science, Mathematical Biosciences, Journal of Mathematical Biology, Carcinogenesis, Science, PNAS, Toxicological Sciences and others

Advisory & Review Committees:

2019-present	Member, UCSF PHRE Science Response Network
2016-2020	Member, World Health Organization Regional Office Europe, Setting research priorities in environment and health
2015 – 2016	Member, Committee to Review the Draft Interagency Report on the Impacts of Climate Change on Human Health in the United States, National Research Council, National Academy of Sciences, USA
2010 – 2016	Member, Science Advisory Group on Electromagnetic Fields and Health, Netherlands Organisation for Health Research and Development

2009 – 2010	Coordinating Lead Author, Interagency Working Group on Climate Change and Health
2009 – 2013	Member, Institute of Medicine Roundtable on Environmental Health Sciences Research and Medicine
2009 – 2012	Member, National Academies of Science Roundtable on Science and Technology for Sustainability
2009	Member, WHO Advisory group on the health implications of the use of DDT to reduce risks of malaria.
2005 – 2010	Chair, Subcommittee on Toxics and Risk, President's National Council on Science and Technology
1997 - 2012	Advisor, *World Health Organization*, International Program on Chemical Safety, EMF Project.
2008 – 2010	Member, Environmental Protection Agency, Science Advisory Board
2007 – 2010	Member, International Life Sciences Institute, Health and Environmental Sciences Institute, Subcommittee on Susceptible Populations
2008	Center Review Committee, Canadian National Science and Engineering Research Council Chair in Risk Assessment
2008	Chair, International Agency for Research on Cancer Monographs Advisory Group, Lyon, France
2008	Advisory Group, Center for Environmental Oncology, University of Pittsburgh Cancer Institute
2007.	Chair, WHO Workshop on Low Cost Options for Reducing Exposures to ELF-EMF, Geneva
2007.	Invited Participant, International Program on Chemical Safety Workshop on Aggregate and Cumulative Risk Assessment, Washington, DC.
2006	Rapporteur, International Agency for Research on Cancer, Scientific Advisory Group to Plan Volume 100 of the IARC Monograph Series
2005	Chair, International Agency for Research on Cancer, Scientific Advisory Board on the Preamble to the Cancer Monograph Series
2005	Chair, World Health Organization Expert Panel on Health Criteria Document for Extremely Low Frequency Electric and Magnetic Fields
2003 – 2005	Co-Chair, Subcommittee on Health and Environment, President's National Council on Science and Technology
2003	Ad-Hoc member, EPA Science Advisory Board, Review of Children's Cancer Risk Assessment Supplement to Cancer Guidelines
2002 – 2006	Co-Chair, Subcommittee on Mercury, President's National Council on Science and Technology
2000 – 2007	Member, Finish Academy of Sciences Centers of Excellence Program Science Advisory Committee
2000	Reviewer, *Congressional Research Service, Library of Congress*; Research needs relevant to children's environmental health risks.
1998 - 2004	Member and Chair, *Environmental Protection Agency*, FIFRA Science Advisory Panel.
1997 - 2006	Member, National Occupational Research Agenda Team, *National Institute of Occupational Safety and Health.*
1995 - 2000	Advisor, *Australian Health Council,* Risk Assessment Methodology, Member *NHMRC* Steering Committee on Cancer Risk Assessment Guidelines.
1992 - 2000	Member, *EPA* Dioxin Reassessment Working Group.

1985 - 2007	Thesis director for graduate students, Department of Biostatistics, *University of North Carolina - Chapel Hill, North Carolina.*
1997	Advisor, *Netherlands National Health Council,* Risk Assessment Methodology.
1997	Reviewer, *Air Force Office of Scientific Research.*
1996 - 1997	Temporary Advisor, *World Health Organization,* Expert Committee on Food Additives.
1996	Advisor, *Environmental Protection Agency;* Evaluation of the benchmark dose methodology.
1996	Advisor, *Environmental Protection Agency;* Evaluation of risks from exposure to PCBs.
1996	Expert Review Committee, *Environmental Protection Agency;* Cancer dose-response for PCB's.
1995 - 1996	Member, *California Environmental Protection Agency,* Risk Assessment Advisory Committee.
1994 - 1997	Science Advisory Panel, *Public Broadcasting System Production* "Poisons in the Womb".
1991 - 1995	Ad-Hoc Member, *Environmental Protection Agency,* Science Advisory Panel.

Legislative Hearings:

- Glyphosate Hearing, European Parliament, Brussels, October, 2017
- Glyphosate Carcinogenicity, European Parliament, Brussels, December 2015
- Glyphosate Carcinogenicity, German Parliament, Berlin, July 2015
- Lead and Children's Health, Senate Committee on Environment and Public Works, July, 2012
- Asthma and Children's Health, Senate Committee on Environment and Public Works, May, 2012
- Contaminated Drywall, Senate Committee on Commerce, Science and Transportation, December, 2012.
- Camp Lejeune Contaminated Drinking Water, House Committee on Science and Technology, September, 2010.
- Autism and Vaccines, House Committee on Government Reform, December, 2002.

US Government Service Activities:

- Member, President's Task Force on Environmental Justice 2010-2013
- Member, President's Task Force on Children's Environmental Health 2009-2013
- Member, National Toxicology Program Executive Committee 2010-2013
- Financial Support and International Press Conference for research on "The Health Benefits of Tackling Climate Change" appearing as a series in Lancet, November 25, 2009
- Organizing Committee, White House Stakeholder briefing on Climate Change and Human Health, Old Executive Office Building, November 2009.
- Member, US Delegation, World Climate Congress, Geneva (September 2009)
- Member, US Delegation, Global Risk Communication Dialogue (2008-2009)
- Member, NIEHS Corrective Action Plan Management Committee (2008-2009)
- Primary focus, all interagency activities on hazards and risk (2006 to present)
- Co-Organizer, NIEHS/EPA Workshop on Children's Environmental Health, RTP, NC, January, (2007)
- Co-Organizer, NIEHS/NTP Workshop on the Identification of Targets for the HTS Roadmap Project (2007)
- Coordinator, NIEHS/EPA Review of the Children's Environmental Health Centers Program (2006-2007)
- Organizing Committee, Global Environmental Health Initiative, NIEHS (2006 to 2009)

- NIEHS Leadership Council (2005 to 2009)
- Organizer, formal collaborative agreements between NTP and Ramazzini Foundation (2001 to 2006)
- Organizer, formal collaborative agreements between NTP and Korean NTP (2002 to 2006)
- NIEHS Title 42 Review Committee (2003 to 2004)
- NIEHS Executive Committee and Operations Update Committee (2000 to 2005)
- NIEHS Leadership Retreats, DERT Retreats, DIR Retreats (all years since 1997)
- Presenter, NIEHS-sponsored National Academy of Sciences Committee on Emerging Issues in Environmental Health, November, 2001
- Organizer and presenter, National Toxicology Program Executive Committee Meetings (multiple dates since 2000)
- Organizer and presenter, National Toxicology Program Board of Scientific Counselors (multiple dates since 1998)
- Organizer, Joint NIEHS/US Geological Survey Interagency Program on Exposure Assessment, April 2001 to present)
- Organizer, US-Vietnam Scientific Conference on the Health and Environmental Effects of Agent Orange/Dioxin in Vietnam, March, 2002
- Organizing Committee, National Toxicology Program/EPA/FDA Scientific Conference on the Allergenicity of Genetically Modified Food, November, 2001
- NIEHS Town Hall Meeting, Los Angeles California, November, 2001
- NTP Research Directions, NAEHSC, Research Triangle Park, NC. May, 2001.
- NCI Study Section Center Presite Meeting, Seattle, Washington, January, 2001.
- Program committee member, *NIEHS/Colorado State University* conference on the Application of Technology to Chemical Mixture Research, 2001.
- Coordinating Core Committee, National Center for Toxicogenomics, NIEHS, 2000 to present
- Organizer, Joint US-Vietnam Consultation on Research on Agent Orange Health Effects in Vietnam. Singapore, 2000
- *ICCVAM/NICEATM*, Up-and-Down Procedure Peer Review Meeting, 2000.
- Chairman, *NIEHS* Risk Assessment Research Committee, 1995-present.
- Discussant, *NIEHS/PNNL* Workshop on Human Biology Models for Environmental Health Effects, 2000.
- Risk Assessment Coordinator, *NIEHS* US *RAPID* Program for the Evaluation of Health Risks from Exposure to Electric and Magnetic Fields, 1996-99.
- Organizer and Chair, Four Public Comment Sessions on the report of the *NIEHS/DOE* Working Group on the Health Effects of Exposure to Electric and Magnetic Fields, 1998.
- Organizer and Co-Chair, *NIEHS/DOE* Working Group on the Health Effects of Exposure to Electric and Magnetic Fields, 1998.
- Scientific Organizing Committee, *NIEHS* Workshop on Risk Assessment Issues Associated with Endocrine Disrupting Chemicals, 1998.
- Organizer, *NIEHS/DOE* Science Research Symposium on the Health Effects of Exposure to Electric and Magnetic Fields I: Biophysical Mechanisms and *In Vitro* Experimentation, 1998.
- Organizer, *NIEHS/DOE* Science Research Symposium on the Health Effects of Exposure to Electric and Magnetic Fields II: Epidemiological Findings, 1998.
- Organizer, *NIEHS/DOE* Science Research Symposium on the Health Effects of Exposure to Electric and Magnetic Fields III: *In Vitro* and Clinical Research Findings, 1998.
- Head, Toxicokinetics Faculty, *NIEHS,* 1994-97.
- Coordinator/Director, *NIEHS/ATSDR* Interagency Course on Mechanistic Modeling in Environmental Risk Assessment, 1996.
- Organizer, *NIEHS/EPA* Workshop on Research Priorities for New Risk Assessment Guidelines,

1996.

- Co-Organizer, *National Institute of Statistical Sciences*, *NIEHS/EPA* Workshop on Mechanistic Modeling in Risk Assessment, 1995.
- Scientific Coordinator and Mission Director, *NIEHS* "Mission to Vietnam" to assess the potential for scientific collaboration on the impact of Agent Orange on the Vietnamese Population, 1995.
- Chairman, *NIEHS* Computer Science Focus Group, 1995.
- Discussant, National Toxicology Program Workshop on Mechanistic Modeling in Toxicology, *NIEHS*, 1995.
- Discussant, National Toxicology Program Workshop on Mechanisms of Carcinogenesis, *NIEHS*, 1995.
- Co-Organizer, International Conference on The Role of Cell Proliferation in Carcinogenesis, co-sponsored by *NIEHS*, *The Chemical Industry Institute of Toxicology*, *The International Life Sciences Institute* and *The American Industrial Health Council*, 1992.
- Organizer and Director, Scientific Basis of Animal Carcinogenicity Testing, Moscow, Russia, co-sponsored by the *International Agency for Research on Cancer*, *NIEHS*, *Health and Welfare Canada* and *The All-Union Cancer Research Center*, 1991.
- Chairman, Computer Technology Advisory Forum, *NIEHS*, 1989.
- Organizer and Director, Design and Analysis of Long-Term Animal Carcinogenicity Experiments, Lyon, France, co-sponsored by the *International Agency for Research on Cancer* and the *NIEHS*, 1988.

Non-Governmental (US) Activities:

- Member, NRC Committee to review the Draft Interagency Report on the Impacts of Climate Change on Human Health in the United States, Washington, DC, 2015
- Expert Scientist, International Agency for Research on Cancer Monograph Meeting on Some Organophosphate Pesticides and Herbicides, Lyon, France, March, 2015
- Overall Chair, International Agency for Research on Cancer Monograph Meeting on Diesel and Gasoline Engine Exhausts and related compounds, Lyon, France, June, 2012
- Advisor to Wellcome Trust at "International Research Futures Symposium on Global Change, Economic Sustainability, and Human Health", London, England, March, 2012.
- Expert Panel Member for review of Hollings Marine Laboratory, National Oceanographic and Atmospheric Agency, Charleston, USA, February, 2012.
- Chair, Mechanism Subgroup, International Agency for Research on Cancer Monograph Meeting on Radiofrequency Electric and Magnetic Fields, Lyon, France, May, 2011
- Advisor, Greek Ministry Health, Working group on hexavalent chromium in the environment, January, 2011
- Member, WHO Consultation on Human Health Risks from DDT, Geneva, Switzerland, November, 2010
- Associate Editor, Frontiers in Predictive Toxicity, 2010 – 2011
- Scientific Advisor, Health Investigation Levels Workshop, Canberra, Australia, January, 2010
- Chair, IARC Working Group, IARC Monograph 100-G, Lyon, France, October, 2009
- Scientific Organizing Committee, VII World Congress on Alternatives and Animal Use in Life Sciences, Rome, Italy, September, 2009
- Chair, Research Directions Working Group, World Health Organization Consultation on Global Research on Climate Change and Health, October, 2008.
- Editor-in-Chief, The Open Environment Journal, May 2008-August, 2010
- Member, EPA Science Advisory Board, July, 2008-present
- Working Group Member, IARC Monograph 98 - Fire-fighting, Painting and Shift-work, Lyon, France, November, 2007

- Chair, WHO Extremely Low Frequency Magnetic and Electric Fields Workshop on Intervention Strategies, June, 2007
- Special Advisor to the Director, Program on Public Health and the Environment, WHO, Geneva, May-July, 2007
- Member, International Life Sciences Institute Working Group on Susceptible Populations, March, 2007 – present
- Special Advisor to the Director, Program on Public Health and the Environment, WHO, Geneva, November, 2006-January, 2007
- Breakout Group Chair, International Workshop on Uncertainty and Variability in PBPK Modeling, RTP, NC USA, October, 2006
- Member, Health Effects Sciences Institute Committee on Sensitive Subpopulations and Groups, Washington, DC, 2006 to present
- Rapporteur, Steering Committee for developing the 100th Monograph of the International Agency for Research on Cancer, Lyon, France, September, 2006
- Co-Organizer, parallel workshops on the advancement of PBPK modeling in risk assessment, Research Triangle Park, November, 2006, Corfu, Greece, April, 2007.
- Organizer, Alternative Models in Developmental Neurotoxicity, Alexandria, Virginia, March, 2006.
- Organizer, NTP High Throughput Screening Workshop, Washington, DC, December, 2005
- Organizer, ISRTP Meeting on Alternative Methods in Toxicology, Baltimore, Maryland, November, 2005
- Organizer, NTP 25th Anniversary Meeting, Washington, DC, May, 2005
- Organizer, IPCS/WHO Workgroup on Dose-Response Modeling, Geneva, Switzerland, September, 2004
- Organizer, Consultation on harmonization of toxicological research between the NTP, Ramazzini Foundation and the European Union, European Congress of Toxicology, Florence, Italy, September, 2003.
- Member, WHO Workgroup on the epidemiology of cellular phone toxicity, Tskuuba, Japan, September, 2003.
- Program Committee, 12th International Conference on Global Warming, Boston, Massachusetts, May 2003
- Program Committee, International Conference on Cancer Risk Assessment, Athens, Greece, August, 2003
- Chair, WHO Public Consultation on Risk Communication, Luxembourg, February, 2003.
- Chair, WHO Committee on Establishing a Plan for Implementation of the Precautionary Principle in Risk Management. Luxembourg, February, 2003.
- Presenter (on behalf of US Government), National Academy of Sciences Panel on the Use of Third Party Toxicity Research with Human Research Participants, December, 2002
- Member, US Science Delegation, United Nations Environmental Program Consultation on Organic Mercury, September, 2002
- Science Panel Member, IARC Carcinogenicity Review of ELF-EMF, Lyon, France, June, 2001.
- Reviewer, Finish Ministry of Health Centers of Excellence Program, Helsinki, April, 2001.
- *EPA* dioxin reassessment peer review workshop and public comment session, Washington, DC, 2000.
- Organizer: Dioxin Dose-Response Working Group Meeting, Fort Collins, Colorado, February, 2000.
- Chair, Spiegelman Award Committee, *American Public Health Association,* 1998.
- Chair, *Bioelectromagnetics Society* Symposium on the use of Transgenic Animals in Evaluating Health Risks from Exposure to Cellular Phones, St. Petersburg, Florida, 1998.

- Member, *World Health Organization* International Program on Chemical Safety, Workshop on Issues in Cancer Risk Assessment, 1998.
- Advisor, *Joint Committee on Food Additives, World Health Organization/Food and Agriculture Organization*. Evaluation of certain food additives and contaminants
- Member, US Government Methylene Chloride Risk Characterization Science Committee, 1996-1998.
- Scientific Organizing Committee, *Colorado State University* Workshop on Biomedical Advances on Chemical Mixtures, 1997.
- *National Academy of Sciences*, Institute of Medicine, Committee on Funding Future Agent Orange Research in Vietnam, 1996.
- Discussant, Workshop on the role of Endocrine Disruptors in Human Health, 1995.
- Advisor to *Australian Health Council* on Risk Assessment Methodology, Member *NHMRC* Steering Committee on Cancer Risk Assessment Guidelines
- Participant, International Program on Chemical Safety of the *World Health Organization* Workshop on Chemical Risk Assessment, London, England, 1995.
- Participant, *IARC* Workshop on Receptor-Mediated Carcinogenesis, Lyon, France, 1994.
- Co-Organizer, Symposium on Quantitative Risk Assessment, *German Cancer Research Center*, Heidelberg, Germany, 1993.
- Participant, *IARC* Monograph on Risk Assessment Methodology, *International Agency for Research on Cancer*, Lyon, France, 1993.
- Thesis advisor for graduate student, *University of Waterloo*, Waterloo, Ontario, Canada. 1991-93.
- Co-Organizer, *Russian Academy of Sciences* Informatics and Cybernetics Research Award, 1992.
- Official Observer, IARC Monograph on the Biological Effects of Ultraviolet Radiation, *International Agency for Research on Cancer*, Lyon, France, 1992.
- Member, *International Life Sciences Institute*, Dose-Response Working Group, 1991.
- Participant in Banbury Conference on Human Health Risks from Exposures to Dioxins, Banbury Conference Center, Cold Spring Harbor, New York, 1990.
- Co-Chairman, Session on Biostatistical Developments in Cancer Research, *15th International Cancer Congress*, Hamburg, Germany, 1990.
- Participant in *Environmental Protection Agency* Workshop on Risk Assessment Guidelines, Virginia Beach, Virginia, 1989.

Direction of Ph.D. Theses:

A Bailer. *The effects of treatment lethality on tests of carcinogenicity*. Department of Biostatistics, University of North Carolina, Chapel Hill, North Carolina, 1986.

P Williams. *Estimating tumor incidence rates using the method of moments and maximum likelihood estimation combined*. Department of Biostatistics, University of North Carolina, Chapel Hill, North Carolina, 1989.

G Carr. *The analysis of data on adverse reactions to chemicals in developmental toxicology*. Department of Biostatistics, University of North Carolina, Chapel Hill, North Carolina, 1989.

S Liu. *Estimating parameters in a two-stage model of carcinogenesis using information on enzyme-altered foci from initiation-promotion experiments*. Department of Biostatistics, University of North Carolina, Chapel Hill, North Carolina, 1993.

CD Sherman. *Multipath/multistage models of carcinogenesis*. Department of Statistics and Actuarial Sciences, University of Waterloo, Waterloo, Ontario, Canada, 1994.

C Lyles. *Cell labeling data: Models and parameter estimation*. Department of Biostatistics, University of North Carolina, Chapel Hill, North Carolina, 1995.

F Ye. *The equal slopes test for benchmark doses*. Department of Biostatistics, University of North Carolina, Chapel Hill, North Carolina, 2001

S Whitaker. *Development of a biologically-based mathematical model of fetal development*. Department of Mathematics, North Carolina State University, Raleigh, North Carolina, 2000.

R Hehns. *Homeostatic feedback control of growth in multistage cancer models*. Department of Biostatistics. University of North Carolina. Chapel Hill. North Carolina. 2001

Genetic-environment interaction

ABSTRACT

Emerging studies have provided evidence on the carcinogenicity of radiofrequency radiation (RFR) from cell phones. This study aims to test the genetic susceptibility on the association between cell phone use and thyroid cancer. Population-based case-control study was conducted in Connecticut between 2010 and 2011 including 440 thyroid cancer cases and 465 population-based controls with genotyping information for 823 single nucleotide polymorphisms (SNPs) in 176 DNA genes. We used multivariate unconditional logistic regression models to estimate the genotype-environment interaction between each SNP and cell phone use and to estimate the association with cell phone use in populations according to SNP variants. Ten SNPs had $P < 0.01$ for interaction in all thyroid cancers. In the common homozygote groups, no association with cell phone use was observed. In the variant group (heterozygotes and rare homozygotes), cell phone use was associated with an increased risk for rs11070256 (odds ratio (OR): 2.36, 95% confidence interval (CI): 1.30–4.30), rs1695147 (OR: 2.52, 95% CI: 1.30–4.90), rs6732673 (OR: 1.59, 95% CI: 1.01–2.49), rs396746 (OR: 2.53, 95% CI: 1.13–5.65), rs12204529 (OR: 2.62, 95% CI: 1.33–5.17), and rs3800537 (OR: 2.64, 95% CI: 1.30–5.36) with thyroid cancers. In small tumors, increased risk was observed for 5 SNPs (rs1063639, rs1695147, rs11070256, rs12204529 and rs3800537), In large tumors, increased risk was observed for 3 SNPs (rs11070256, rs1695147, and rs396746). Our result suggests that genetic susceptibilities modify the associations between cell phone use and risk of thyroid cancer. The findings provide more evidence for RFR carcinogenic group classification.

1. Introduction

The International Agency for Research on Cancer (IARC) classified radiofrequency radiation (RFR) emitted from cell phone as possible human carcinogen (Group 2B) in 2011 based on limited evidence from humans (IARC Working Group, 2013). One cohort study (Schuz et al., 2006) and five case-control studies (Auvinen et al., 2002; Hardell et al., 2011; Inskip et al., 2001; INTERPHONE Study Group, 2010; Muscat et al., 2000) were evaluated by the IARC Working Group. Brain tumors including glioma, acoustic neuroma, and meningioma were evaluated in these studies. Two studies observed an increased risk of brain tumor in people with the highest cumulative cell phone use (Hardell et al., 2011; INTERPHONE Study Group, 2010). Though these studies were vulnerable to methodological limitations and possible biases, such as no appropriate evidence-based metric for cell phone use, the working group stated that positive associations have been observed between exposure to radiofrequency radiation and glioma, and acoustic neuroma (IARC Working Group, 2013). Most group members agreed that positive associations in these studies could not be dismissed and that it was appropriate to classify RFR as a Group 2B carcinogen (Baan et al., 2011).

Since 2011, emerging studies have offered additional evidence on

the carcinogenicity of RFR. An animal experiment published in 2018 by the National Toxicology Program (NTP) concluded that there was clear evidence to support an association between RFR exposure from cell phones and tumors in the hearts and brains of male rats (National Toxicology Program, 2018a; National Toxicology Program, 2018b; Wyde et al., 2018). These findings were confirmed by another animal study from the Ramazzini Institute (Falcioni et al., 2018). Additional population studies have also been published since the IARC classification. Nine articles using data from case-control studies concluded that long-term cell phone use was associated with an increased risk of brain tumor (Aydin et al., 2011; Cardis et al., 2011; Carlberg and Hardell, 2012; Coureau et al., 2014; Grell et al., 2016; Hardell and Carlberg, 2015; Hardell et al., 2013; Momoli et al., 2017). Two cohort studies did not observe an association between cell phone use and brain tumor (Benson et al., 2013; Frei et al., 2011). However, one study (Benson et al., 2013) only provided baseline exposure and another study (Frei et al., 2011) used mobile phone subscription. The limitations of exposure assessment suffered from these two cohort studies might render their null associations uninformative (Söderqvist et al., 2012). These new findings build up researchers' concerns about health effects of cell phone use and support the effort to reclassify RFR as a Group 1 carcinogen (Miller et al., 2018). A new report from IARC advisory group also recommended a re-evaluation of RFR classification (IARC, 2019).

Cell phone technology has changed over the past three decades. The analog cell phone was introduced to the US in 1983 and then digital cell phone in 1993. In 2008, the US Federal Communications Commission officially let American carriers decommission analog network (Scherer, 2018). Cell antennas tend to be located at the bottom of cell phones since the introduction of smartphone around 2010, and thus the peak RFR exposure is more likely to occur in the neck than in the brain (Carlberg et al., 2016). Thyroid gland located in the neck is the most radiation-sensitive organ (Zhang et al., 2015); and the only established exogenous risk factor for thyroid cancer is ionizing radiation (Sinnott et al., 2010). A recent study linked cell phone use with thyroid cancer (Luo et al., 2019), though only borderline significant results were observed. Thyroid cancer incidence rates have been rising substantially over the past several decades, paralleling the increased use of cell phones. Therefore, more studies are needed to investigate whether RFR from cell phones contributes to the increase.

It is suggested that in addition to thermal effects, the energy from RFR is sufficient to alter the structure and function of proteins involved in DNA damage repair (Phillips et al., 2009). Recent studies indicated that exposure to RFR increased DNA damage (Smith-Roe, 2019; Yakymenko et al., 2016). However, genetic factors were not considered in previous epidemiologic studies. To our knowledge, no epidemiologic studies have examined gene-environment interactions.

Given the potential relationships between RFR from cell phone use, thyroid cancer and DNA damage repair, this study aims to investigate the role of DNA repair genes in the association between cell phone use and thyroid cancer using data from a population-based case-control study in Connecticut, USA. We hypothesize that variants of single nucleotide polymorphisms (SNPs) within DNA repair genes can modify the effects of RFR from cell phone use.

2. Method

2.1. Study population

Details of the population-based case-control study were described in previous publications (Luo et al., 2019; Sandler et al., 2018). In brief, the study included 462 histologically confirmed incident thyroid cancers (papillary (ICD-O-3: 8050, 8052, 8130, 8260, 8340–8344, 8450, and 8452), follicular (ICD-O-3: 8290, 8330–8332, and 8335), medullary (ICD-O-3: 8345, 8346, and 8510), or anaplastic (ICD-O-3: 8021)) diagnosed between 2010 and 2011 in Connecticut (375 females and 87 males), and 498 population-based controls (344 females and 154 males). All cases were between 21 and 84 years old, without previous cancer except nonmelanoma skin cancer, and were alive at the time of interview. A total of 701 eligible cases were identified and 462 (65.9%) completed in-person interviews. Controls were recruited through random digit dialing. A total of 498 controls joined the study with a participation rate of 61.5%. All participants, including cases and controls in this study, were interviewed by trained study interviewers using a standardized and structured questionnaire to collect information on demographics, cell phone use, radiation exposure, lifestyle factors, occupation, and diet. Cases and controls were frequency-matched by age (± 5 years). The study was approved by the Human Investigations Committee at Yale and the Connecticut Department of Public Health. Written informed consent was obtained from all participants.

[a] Benign thyroid disease included hyperthyroidism, hypothyroidism, goiter, thyroid nodules, and thyroid adenoma.

[b] Ever alcohol consumption was defined as ever had more than 12 drinks of alcoholic beverages such as beer, wine, or liquor. 1 drink of beer = 1 can or bottle; 1 drink of wine = 14 oz glass; 1 drink of liquor = 1 shot.

[c] p values from chi-square test were used to test the difference between cases and controls.

2.2. Cell phone use assessment

The participants were asked the following questions regarding the frequency, duration, and protective behaviors of cell phone use: (1) Have you ever used a cell phone at least once a week for 6 months prior to one year before diagnosis? (2) What calendar year did you start regularly using a cell phone? (3) What calendar year did you stop regularly using a cell phone? (4) Excluding the time period that you did not use a cell phone, altogether how many years have you regularly used a cell phone? (5) What proportion of the time did you use a hands-free device when you regularly used a cell phone? (6) On average, how

[a] Adjusted for age (continuous), sex (male, female), education (< college, college, > college), family history of thyroid cancer (yes, no), alcohol consumption (yes, no), body mass index (BMI, < 25, 25–29.9, ≥30), and previous benign thyroid diseases (yes, no).
[b] Interaction between cell phone use and SNP variants.
[c] Q values are adaptive P values that control for the positive false discovery rate.

many phone calls did you make or receive per day? (7) On average, how many hours per day did you use a cell phone? If a participant answered "Yes" to question (1), he/she was defined as a "cell phone user" and otherwise a "cell phone non-user". Information on cordless phone use was not collected in our study. Phone use hours per day, phone calls per day and phone use years were calculated from these variables. These variables were categorized into two halves based on the median values.

2.3. SNP genotyping

After undergoing the standardized interview process described previously, a total of 448 thyroid cancer cases (356 females and 84 males) and 465 controls (320 females and 145 males) donated samples of whole blood by venipuncture. Peripheral blood leukocyte DNA was extracted using the Qiagen Phenol-Chloroform Extraction Kit (Qiagen, N.V.) according to standard manufacturer protocol. DNA was then genotyped using a custom-made Illumina GoldenGate assay. Genotyping data were successfully obtained for 440 thyroid cancer cases and 465 controls. The GoldenGate assay included analysis of 878 SNPs in 177 gene regions involved in DNA repair. Quality control duplicate samples were also included in the genotyping platform. All duplicate samples yielded a concordance rate of ≥99%. The Hardy–Weinberg equilibrium (HWE) was assessed in controls for each SNP using a chi-squared test. SNPs with a $P > 0.00001$ from the chi-squared test were considered to be in HWE. Of the 878 SNPs tested, 55 SNPs were not in HWE and were excluded from the final analyses.

2.4. Statistical analysis

Unconditional logistic regression models were employed to evaluate the associations of SNP variants and cell phone use. Each SNP was categorized into two groups: common group (common homozygote) and variant group (heterozygote and rare homozygote combined). First, we evaluated the interaction between cell phone use and SNP variants by adding a cross-product term between SNP variant (common/variant) and cell phone use (user/non-user) as well as product terms between SNP variant and all covariates in the model, including cell phone use. SNPs with a $P < 0.01$ for interaction with cell phone use were selected. A significance level of 0.01 was used for the interaction term rather than a Bonferroni correction because the Bonferroni correction is usually conservative (Bender and Lange, 1999; Perneger, 1998). The Bonferroni correction was used for independent SNP test but rarely for interactions (Conneely and Boehnke, 2007). Currently, there is no consensus on the magnitude of significance level for interaction and a conservative P value may go against the precautionary principle. Additionally, Bonferroni correction fails to simultaneously address type 1 errors as well as the correlated nature in multiple tests (Conneely and Boehnke, 2007). In this case, a significance level of 0.01 can substantially reduce the false claims of significance and thus it is used for interaction. Further, we computed the Q values to control for positive false discovery rate (Storey, 2002; Storey et al., 2004). The Q value is proposed as an alternative to control for multiple tests and reduce false positive.

Second, we stratified the study population according to each selected SNP and re-run the regression to evaluate the associations of cell phone use in each stratum. Odds ratios (OR) and 95% confidence interval (95% CI) of cell phone use were calculated. Considering these

Table 3
Associations of cell phone use on small and large thyroid tumors in populations stratified by SNP variants.

[a] Adjusted for age (continuous), sex (male, female), education (< college, college, > college), family history of thyroid cancer (yes, no), alcohol consumption (yes, no), body mass index (BMI, < 25, 25–29.9, ≥30), and previous benign thyroid diseases (yes, no).
[b] The number of controls can be found in Table 2.

selected SNPs might be correlated, we used Haploview to analyze the linkage disequilibrium (LD) and haplotype among these SNPs (Barrett et al., 2005).

Because small and large thyroid cancers may represent different disease entities, the cases were further stratified by tumor size into small group (≤10 mm) and large group (> 10 mm). The analysis was performed again in the small and large groups, respectively. Additionally, cell phone users in this study were further stratified based on the median values of daily use hours, daily phone calls and phone use years, aiming to examine the impacts of cell phone use frequency and duration on thyroid cancer. A trend test was performed using stratum-specific median values.

All models were adjusted for age (continuous), sex (male, female), education (< college, college, > college), family history of thyroid cancer (yes, no), alcohol consumption (yes, no), body mass index (BMI, < 25, 25–29.9, ≥30), and previous benign thyroid diseases (yes, no). Additional adjustment for variables, including occupational radiation exposure, radiation treatment, race, smoking, family income, diagnostic radiation exposure, dietary intake of seafood and iodine intake did not substantially change (10%) the observed associations; therefore, these variables were not included in the final models. Less than 2% participants had missing values in education and BMI. Multiple imputation was used to generate missing values in covariates. 10 simulated datasets were generated and standard analytical procedures were performed for complete data as proposed (Yuan, 2010).

A significance level of 0.05 was used for statistical inferences other than interaction in this study. All P values in this study are two-sided. All analyses were performed using SAS (version 9.4; SAS Institute Inc., Cary, North Carolina, USA).

3. Results

Table 1 shows the distributions of selected demographic characteristics in cases and controls. The distribution was similar in this subset with blood samples and genotyping compared to those from the full study population (Luo et al., 2019). The independent association of cell phone use in this population can be found in Supplementary Table S1. Supplementary Table S2 lists all SNPs analyzed in this study grouped by genes. The associations between SNPs and thyroid cancer among this population were evaluated and the result can be found in another previous study (Sandler et al., 2018).

Table 2 shows the association between cell phone use and thyroid cancer risk stratified by SNP variants that were observed to have $P < 0.01$ for interaction. In total, there were 10 SNPs from 7 genes including *PAK6* (rs11070256), *MDM2* (rs1695147), *HDAC4* (rs6732673, rs1063639, rs843458), *GATA4* (rs3757949), *UBE2V1* (rs6125888), LINC00336 (rs396746) and *DACT2* (rs12204529, rs3800537). All these SNPs had a Q value less than 0.10, a threshold value that was widely used for interaction (Brouwers et al., 2013). None of these SNPs was independently associated with thyroid cancer in this study population (Supplementary Table S3). In the common SNP group, no association was observed. In the variant group, cell phone use was observed to be significantly associated with an increased risk of thyroid cancer for 6 SNPs: *PAK6* rs11070256 (OR: 2.36, 95% CI: 1.30–4.30), *MDM2* rs1695147 (OR: 2.52, 95% CI: 1.30–4.90), *HDAC4* rs6732673 (OR: 1.59, 95% CI: 1.01–2.49), *LINC00336 rs396746* (OR: 2.53, 95% CI: 1.13–5.65), *DACT2* rs12204529 (OR: 2.62, 95% CI: 1.33–5.17) and *DACT2* rs3800537 (OR: 2.64, 95% CI: 1.30–5.36). SNPs with an interaction $P < 0.10$ can be found in Supplementary Table S4.

	AG/GG	6	38	1.00	39	38	2.93 (1.28–6.72)	32	26	3.38 (1.39–8.22)	0.0088

[a] Adjusted for age (continuous), sex (male, female), education (< college, college, > college), family history of thyroid cancer (yes, no), alcohol consumption (yes, no), body mass index (BMI, < 25, 25–29.9, ≥30), and previous benign thyroid diseases (yes, no).

Table 3 shows the results between cell phone use and thyroid cancer according to SNP variant groups when the cases are restricted to small or large tumors. In the common SNP group, no increased risk of thyroid cancer was observed, which is consistent with previous findings. In the variant group, the results were interesting. In small tumors, cell phone use was observed to be associated with increased risk of thyroid cancer for *PAK6* rs11070256 (OR: 2.33, 95% CI: 1.06–5.12), *MDM2* rs1695147 (OR: 2.29, 95% CI: 1.01–5.19), *HDAC4* rs1063639 (OR: 1.68, 95% CI: 1.00–2.82), *DACT2* rs12204529 (OR: 3.52, 95% CI: 1.37–9.09), and *DACT2* rs3800537 (OR: 4.10, 95% CI: 1.44–11.70). In large tumors, cell phone use was observed to be associated with increased risk of thyroid cancer for *PAK6* rs11070256 (OR: 2.48, 95% CI: 1.14–5.37), *MDM2* rs1695147 (OR: 2.64, 95% CI: 1.10–6.34), and *LINC00336* rs396746 (OR: 4.64, 95% CI: 1.40–15.4). The associations were observed in both small and large tumors for *PAK6* rs11070256 and *MDM2* rs1695147.

Table 4, 5 and 6 show the associations of cell phone use frequency (daily use hours and daily phone calls) and duration (cell phone use years), respectively. In the variant group, some trends were observed. As the daily use hour increased, the risk of thyroid cancer increased for *PAK6* rs11070256 (P_{trend} = 0.0041), *MDM2* rs1695147 (P_{trend} = 0.0156), *HDAC4* rs6732673 (P_{trend} = 0.0154), *HDAC4* rs1063639 (P_{trend} = 0.0106), *DACT2* rs12204529 (P_{trend} = 0.0074) and *DACT2* rs3800537 (P_{trend} = 0.0088). Similarly, as the number of daily phone call increased, the risk of thyroid cancer increased for *PAK6* rs11070256 (P_{trend} = 0.0016), *MDM2* rs1695147 (P_{trend} = 0.0076) and *LINC00336* rs396746 (P_{trend} = 0.0077). For the phone use duration, as the cell phone use year increased, the risk of thyroid cancer increased for *LINC00336* rs396746 (P_{trend} = 0.0340), *DACT2* rs12204529 (P_{trend} = 0.0099) and *DACT2* rs3800537 (P_{trend} = 0.0164).

In Haplotype analysis, no correlation was observed among the 10 selected SNPs, except for rs12204529 and rs3800537, which are both on gene *DACT2*.

4. Discussion

In this first study examining the combined influence of genetic susceptibility and cell phone use in relation to thyroid cancer, we observed interactions between cell phone use and SNP variants. In the variant groups for 6 SNPs, cell phone use was associated with a higher risk of thyroid cancer. The increased risk varied across tumor sizes depending on the SNPs: the increased risk was observed in both small and large thyroid tumors for *PAK6* rs11070256 and *MDM2* rs1695147, but only in small tumors for *HDAC4* rs1063639, *DACT2* rs12204529 and *DACT2* rs3800537, and only in large tumors for *LINC00336* rs396746. Furthermore, associations of increased thyroid cancer risk within variant groups were also observed for increasing cell phone use frequency and duration. Our results suggest that genetic susceptibilities modify the associations between cell phone use and risk of thyroid cancer and identify potential susceptible subgroups.

Proteins encoded by genes selected in this study play important roles in tumor suppression or growth. The PAK6 protein is a member of the p21-activated kinases family and associated with apoptosis. PAK6 can either promote tumor growth by inhibiting cell apoptosis (Chen et al., 2015), or suppress tumor growth through Ser-578 phosphorylation of the androgen receptor and Thr-158 and Sre-186 phosphorylation of the AR-E3 ligase MDM2 (Liu et al., 2013).

MDM2 protein is a key regulator of cell apoptosis. It controls p53 in an autoregulatory feedback loop (Oliner et al., 1993). Furthermore, p53 is a tumor suppressor and can regulate apoptosis and ferroptosis (Xie et al., 2017), an apoptosis-independent form of cell death. By repressing

[a] Adjusted for age (continuous), sex (male, female), education (< college, college, > college), family history of thyroid cancer (yes, no), alcohol consumption (yes, no), body mass index (BMI, < 25, 25–29.9, ≥30), and previous benign thyroid diseases (yes, no). s.

p53 (Boyd et al., 2000), MDM2 can promote tumor growth.

HDAC4 protein promotes deacetylation of histone and non-histone proteins, leading to chromatin condensation and transcriptional repression (Glozak and Seto, 2007). HDAC4 upregulation has been reported to promote cancer in many studies (Colarossi et al., 2014) and its inhibitors have also been reported to suppress tumor growth (Ahn et al., 2012).

GATA4 was selected for interaction though no significant association with cell phone use was observed in *GATA4* variant group. *GATA4* can activate the transcription factor NF-κB to initiate the senescence-associated secretory phenotype, a pro-inflammatory response linked to tumor promotion (Kang et al., 2015). It has been reported to promote ovarian tumors and testicular tumors.

UBE2V1 is also selected in the study but no significant association was observed in the variant group. *UBE2V1* mediates degradation of Sirt1 by ubiquitination, inhibiting histone H4 lysine 16 acetylation, and then epigenetically suppresses autophagy gene expression and promotes cancer metastasis (Shen et al., 2018). Meanwhile, it has also been reported to suppress differentiation of carcinoma cell lines by inhibiting CDK1 then altering cell cycle distribution (Sancho et al., 1998).

LINC00336 is under-investigated and its relevant molecular pathways are unknown. *LINC0*0336 has been observed to be associated with ferroptosis in a recent study. In lung cancer, overexpression of *LINC00336* inhibits ferroptosis and hence promotes tumor growth (Wang, 2019).

DACT2 protein is regulated by promoter region hypermethylation and serves as a tumor suppressor in various cancers including thyroid cancer (Zhao et al., 2014), through intervention in the Wnt and/or TGF-β signaling pathways (Hou et al., 2013).

We observed significant associations between cell phone use and thyroid cancer in variant groups for some SNPs, though none of the SNPs are involved in gene editing. SNP rs1063639 is a synonymous variant and the other SNPs are within introns. However, genetic variants within introns can also be correlated with variants within exons or other regions that directly affect gene expression. In this study, except for SNPs in gene *HDAC4*, other SNPs are highly correlated (LD $r^2 > 0.90$) with at least one SNP in functional genetic regions within a window size of 500,000 bases (Table S5; Correlations were calculated using Ensembl (Zerbino et al., 2018)). Moreover, SNPs within introns might affect RNA splicing patterns and thus downregulate or upregulate key protein products (Chorev and Carmel, 2012). Overall, though SNPs selected in this study are within introns, they may still imply possible genetic interactions with environmental factors.

When interpreting the study findings, potential limitations must be considered. First, we used a significance level of 0.01 for interaction rather than the conservative Bonferroni correction. However, we used the Q value to control for false discovery rate. All selected SNPs in this study had a Q value less than 0.10, a threshold value that was widely used for interaction (Brouwers et al., 2013), suggesting one false positive be expected in this study. Therefore, false positive is not a major concern in this study. A strong significance test should lie on the biological plausibility and reproduction of our observations in independent cohorts. Given the public health importance, we call for more studies to continue the investigation on the interaction between cell phone use and genetic variants. Second, cell phone use was assessed using questionnaires in this study and thus the exposure classification and recall bias cannot be ruled out. As discussed in the previous article (Luo et al., 2019), there was no evidence linking cell phone use and thyroid cancer that could have influenced participant's risk perception. Additionally, increased risks were only observed in the variant group. If the increased

Table 6
Associations of cell phone use year on the risk of thyroid cancer in populations stratified by SNP variants.

[a] Adjusted for age (continuous), sex (male, female), education (< college, college, > college), family history of thyroid cancer (yes, no), alcohol consumption (yes, no), body mass index (BMI, < 25, 25–29.9, ≥30), and previous benign thyroid diseases (yes, no).

risks had been due to bias or chance, they should have been observed in the common SNP group as well. Overall, though we cannot completely rule out recall bias and exposure misclassification, they were likely to be non-differential and resulted in an underestimation of the true association.

This study was conducted between 2010 and 2011, when it was still possible to recruit enough cell phone non-users, which is a strength of this study. Most of these non-users were nearly 10 years older than users (mean age: 59.2 vs. 50.5). Today with the popularity of cell phones, it is difficult to recruit enough non-users as in this study. It is also noteworthy that at that time, only a small proportion of people had smart phones. Therefore, if cell phone use increased the risk of thyroid cancer, it was possibly due to use of earlier generation of cell phones. The thyroid gland is exposed to more RFR emitted from smart phones compared to earlier generations of cell phone and thus smart phones may pose a greater risk. As a result, findings from this study warrant a further evaluation in future studies.

Given these findings in conjunction with the IARC classification and recent additional studies, we suggest a precautionary approach to cell phone use. Approaches for reducing cell phone radiation include the usage of hands-free devices, limited cell phone use among teenagers, and recommendation for low power cell phone mode. However, the associations observed in this study do not necessarily imply a complete restriction of cell phone use, especially given the important roles of cell phones in today's life. Further evaluation is needed.

In conclusion, this study found that cell phone use increased the risk of thyroid cancer when genetic variants were present within some genes. Our study suggests that pathways related to DNA repair may be involved in the cell phone-thyroid carcinogenesis. This study identifies potential susceptible subgroups. More studies are urgently needed to confirm our findings and explain the mechanisms behind the interactions between genetic variants and cell phone use.

Lost opportunities for cancer prevention: historical evidence on early warnings with emphasis on radiofrequency radiation

https://doi.org/10.1515/reveh-2020-0168
Received December 16, 2020; accepted January 30, 2021; published online February 15, 2021

Abstract: Some historical aspects on late lessons from early warnings on cancer risks with lost time for prevention are discussed. One current example is the cancer-causing effect from radiofrequency (RF) radiation. Studies since decades have shown increased human cancer risk. The fifth generation, 5G, for wireless communication is about to be implemented world-wide despite no comprehensive investigations of potential risks to human health and the environment. This has created debate on this technology among concerned people in many countries. In an appeal to EU in September 2017, currently endorsed by more than 400 scientists and medical doctors, a moratorium on the 5G deployment was required until proper scientific evaluation of negative consequences has been made (www.5Gappeal.eu). That request has not been taken seriously by EU. Lack of proper unbiased risk evaluation of the 5G technology makes adverse effects impossible to be foreseen. This disregard is exemplified by the recent report from the International Commission on non-ionizing radiation protection (ICNIRP) whereby only thermal (heating) effects from RF radiation are acknowledged despite a large number of reported non-thermal effects. Thus, no health effects are acknowledged by ICNIRP for non-thermal RF electromagnetic fields in the range of 100 kHz–300 GHz. Based on results in three case-control studies on use of wireless phones we present preventable fraction for brain tumors. Numbers of brain tumors of not defined type were found to increase in Sweden, especially in the age group 20–39 years in both genders, based on the Swedish Inpatient Register. This may be caused by the high prevalence of wireless phone use among children and in adolescence taking a reasonable latency period and the higher vulnerability to RF radiation among young persons.

Keywords: asbestos; cancer prevention; DDT; dioxins; early warnings; glyphosate; phenoxyacetic acids; radiofrequency radiation; tobacco.

Introduction

The International Agency for Research on Cancer (IARC) at the World Health Organization (WHO) initiated in 1969 a program to evaluate human cancer risks of chemicals. It was later expanded to include chemical mixtures, radiation and viruses. So far, this program has resulted in 125 Monographs. Mostly, as the history shows, it has taken a long time between the first reports of increased cancer risk and cancer classification of the agent. Thereby preventive measures have not been taken in due time with high costs to society as a consequence in terms of increased numbers of cases with diseases leading to suffering and costs for treatment, loss of professional activity and eventually premature deaths [1–3]. Thus, early warnings should not be neglected. In fact, false positives on environmental risks are extremely rare [4]. In the following some historical examples are discussed, followed by a review of the current controversy on radiofrequency (RF) radiation and cancer. These examples serve as lessons for early warnings [5, 6].

No doubt the reports from the European Environment Agency on late lessons from early warnings may serve as important documents for the precautionary approach. Volume 1 was published in 2001 [5]. It dealt with 12 key lessons on health and environmental hazards. The 2013 volume on late lessons was grouped into five parts including e.g., health, ecosystems, justice, and governance [6]. Both volumes give examples on action that could have been taken to prevent harm. In the following some examples are discussed partly based on our own research experiences.

Examples of early warnings on cancer risks

The first history on occupational diseases was written by the Italian physician Bernardini Ramazzini in his book "De morbis artificum" (Diseases of Workers) printed in Modena, Italy 1700. He is regarded to be the 'father of occupational medicine'. A second extended version was printed in Padua 1713. In the book 53 chapters deal with different occupations and diseases occurring in these occupations [7].

Regarding specific occupational exposures the English physician Percival Pott was the first to describe that men working as chimneysweeps, and thereby exposed to soot, had an increased risk for scrotal cancer. He published his findings in 1775 [8]. This disease was known as chimney-sweepers' cancer. It is regarded to be the first report of an environmental factor causing cancer. It took a long time of campaigning to stop little boys being used to clean chimneys by climbing up them. More than 200 years later soot was classified as a human carcinogen Group 1 (carcinogenic) by IARC in 1985 [9].

Asbestos

Another both occupational and environmental toxic substance is asbestos. Already in 1899, a UK Factor Inspector observed the sharp glass-like jagged nature of asbestos particles [10]. The author noted asbestos dust in the air of the factory rooms and that "*the effects have been found to be injurious*". Numerous reports have since then described increased risks primarily of lung cancer and mesothelioma. Already in 1935, a man with asbestosis and lung cancer was reported [11]. In 1953 it was reported that a man who had worked with asbestos died of pleural mesothelioma [12]. South African researchers published in 1960 a report on increased risk for mesothelioma for both occupational and environmental exposure to asbestos [13]. The American physician Dr. Irving Selikoff gave to a broader public insight into a dramatic increased cancer mortality among American insulation workers exposed to asbestos. Also, that environmental exposure increased the risk of mesothelioma [14]. This started a long-standing battle between a multinational industry defending its product, and public health and regulatory bodies [15, 16]. Asbestos was in 1977 evaluated by IARC to be carcinogenic to humans, Group 1 [17]. This was almost 20 years since the clear evidence of cancer risks was published in the early 1960s. Years were lost for prevention and yielded increased numbers of deaths.

Tobacco

Tobacco has a long history of reported adverse health effects. When first introduced in Europe smoking was recommended for medical purposes, in fact as prophylaxis for many diseases. In 1604 King James I of United Kingdom wrote against the use of tobacco [18]. Sömmering stated in a thesis in 1795 that tobacco pipes induced an increased risk for lip cancer [19]. Cancer of the tongue was described some 100 years later in 1890 [20]. A high proportion of diseases including lung cancer among cigar makers and sellers, waiters, and innkeepers was reported in 1914 [21]. A clearly increased incidence of lung cancer was first reported by Müller in 1940 [22]. This evidence and other cancer studies in the 1940s in Germany [23] and in the Netherlands [24] were mainly disregarded thereby omitting the possibility of early prevention. It was not until the 1950s when more studies showed health risks from tobacco, primarily for diseases such as cancer of the lung, myocardial infarction, peripheral vascular diseases, and chronic obstructive lung disease. Tobacco was in 1986 classified by IARC as a human carcinogen, Group 1 [25]. No doubt the history of smoking shows that early warnings were mainly neglected. Greenwashing by industry and its allied experts has a history of counteracting preventive measurements [26].

DDT

The marine biologist Rachel Carson was the first to write a general picture of chemical damage to the environment, human and animal health in her book Silent Spring published in 1962 [27]. She gave the first comprehensive description of the bioaccumulation of the insecticide DDT (*para,para'*-DDT –1,1'-(2,2,2-trichloro-ethylidene)bis (4-chloro benzene)). DDT was discovered in 1939 by the Swiss researcher Paul Müller. For that he received the Nobel Prize in medicine in 1948. No doubt the book by Rachel Carson was opposed by the chemical industry that even tried to stop the publication. In fact, DDT was defended by the American Medical Association and the US Nutrition Foundation unified with 54 companies in the food, chemical and allied industries [28]. The main human studies on human carcinogenicity of DDT and its main metabolite DDE (1,1'-(2,2-dichloroethenylidene)- bis(4-chlorobenzene)) were performed from the 1990s and onward [29].

The Stockholm Convention on Persistent Organic Pollutants was adopted in 2001. It provided initially evidence for the elimination of 12 chemicals, one of which was DDT [30]. The use of DDT was banned in most countries in the 1970s [31]. In 1972, the US EPA issued a cancellation order for DDT [32]. DDT was evaluated by IARC in 2018 to be probably carcinogenic to humans, Group 2A [29]. It had previously been evaluated as a possibly human carcinogen, Group 2B [33]. One of the main toxic issues is the bioaccumulation of DDT and its metabolites with long half-time in the environment [27]. DDT is still used in some countries, e.g. for malaria control. Due to its chemical behavior its metabolites can be found in human tissue [34, 35].

Phenoxyacetic acids

In 1977, a report was published on a series of patients who had been spraying phenoxy herbicides for the Swedish Forestry and who subsequently developed soft-tissue sarcoma [36]. Herbicides of this type include 2,4-dichlorophenoxyacetic acid (2,4-D) and 2,4,5-trichlorophenoxyacetic acid (2,4,5-T). 2,4,5-T was contaminated by 2,3,7,8,tetrachlorodibenzo-p-dioxin (TCDD), one of the most toxic chemicals in the world. This clinical observation was the first to indicate a possible increased cancer risk for these chemicals. Based on that report an increased risk for soft-tissue sarcoma was found both for these phenoxy herbicides and the chemically related chlorophenols, mostly exposure to pentachlorophenol, in a following case-control study [37]. These results were corroborated in further studies by our research group and others, for an overview see [2].

Another set of studies included malignant lymphoma, also initiated by a clinical observation [38]. This clinical observation resulted in further studies. An increased risk was found for both non-Hodgkin lymphoma (NHL) and Hodgkin's disease for persons exposed to phenoxy herbicides or chlorophenols [39]. Also, the increased lymphoma risk was confirmed in other studies, for overview see [2, 40].

One of the main types of chlorophenols, pentachlorophenol, was classified by IARC in 2019 to be carcinogenic to humans, Group 1 [41]. The phenoxy herbicide 2,4-D was in 2018 classified by IARC as possibly carcinogenic to humans, Group 2B [29]. It was the same classification as in 1977 including also 2,4,5-T [42].

Dioxins

The phenoxy herbicides 2,4-D, 2,4,5-T and chlorophenols were contaminated with dioxins. Of large concern was TCDD that contaminated 2,4,5-T and trichlorophenol. The initial Swedish results on cancer risks from this group of chemicals were followed by studies in other countries that confirmed the findings, for overview see [2,40]. Vietnam veterans exposed to the defoliating agent Agent Orange, including 2,4-D and 2,4,5-T, with TCDD contamination suffering from soft-tissue sarcoma or malignant lymphoma were in 1991 judged to be eligible for service-related compensation [43].

In 1976 an accident occurred in a chemical plant at Seveso, Italy producing 2,4,5-trichlorophenol. Thereby the surrounding area was contaminated with dioxins and the general population was exposed to TCDD. In the aftermath an increased incidence in malignant diseases, notably soft-tissue sarcoma and hematolymphatic malignancies was found in the population [40, 44].

Various *ad hoc* explanations were postulated by the chemical industry and its allied experts to discredit the cancer risks [2]. However, in 1997 IARC classified TCDD as a human carcinogen, Group 1 [45]. It had previously been evaluated in 1977 by IARC to be a possibly human carcinogen, Group 2B [42]. This was about two decades after the first epidemiological publications on increased cancer risk for TCDD contaminated herbicides.

Glyphosate

In the case-control studies by the Hardell group on risk factors for NHL exposure to all types of herbicides was assessed. In addition to phenoxyacetic acids also glyphosate turned out to increase the risk [46, 47]. Hairy cell leukemia (HCL) is regarded to be a subtype of NHL. In a separate study on HCL glyphosate was a risk factor also for that malignancy [48]. Similar results were also found in other studies [49, 50].

Glyphosate was in 1970 tested as herbicide and was patented by Monsanto [51]. It was registered for use in USA in 1974 with the trade name 'Roundup'. Since the patent has expired it is produced nowadays by many manufactures. In 1996 genetically engineered glyphosate tolerant crops were introduced (Roundup Ready) and since then the global use has increased 15-fold. Glyphosate has in recent years been the most widely used pesticide [52].

IARC at WHO evaluated glyphosate in March 2015 and classified it as a Group 2A, a probable human carcinogen [53, 54]. This was based on "limited" evidence of cancer in humans (from real-world exposures that occurred) and "sufficient" evidence of cancer in experimental animals (from studies of "pure" glyphosate). IARC also concluded that there was "strong" evidence for genotoxicity, both for "pure" glyphosate and for glyphosate formulations.

The European Food Safety Authority (EFSA) is the EU agency for risk assessment regarding food safety. In October 2015, that is seven months after the IARC evaluation, EFSA published its own evaluation [55]. In summary EFSA dismissed without clear explanation any association of glyphosate with cancer. All findings on carcinogenesis in animal studies were incorrectly discarded as chance findings. Mechanistic evidence on genotoxicity was ignored. Oxidative stress was confirmed but dismissed as a ground for carcinogenesis [56]. It should be noted that EFSA did not reveal the names of the authors of the chapters and references were redacted.

Monsanto, the main glyphosate producer, hired a panel of scientists to defend glyphosate. Thus, in 2016 a 17-page article was published in Critical Reviews in Toxicology, known to be an industry friendly product defense journal [57]. It was concluded that "*In summary, the totality of the evidence, especially in light of the extensive testing that glyphosate has received, as judged by the Expert Panels, does not support the conclusion that glyphosate is a "probable human carcinogen" and, consistent with previous regulatory assessments, the Expert Panels conclude that glyphosate is unlikely to pose a carcinogenic risk to humans.*"

This review was made by four expert panels. In the initial publication no conflicts of interest were stated. All but six of the 16 authors appeared with their university or hospital affiliation. During lawsuits in USA on glyphosate exposure and NHL it was revealed that the authors were not independent, and that Monsanto was deeply involved in organizing, reviewing and editing the review. In fact, Monsanto paid the authors through a consulting firm, *Intertek* [58].

As a consequence Critical Reviews in Toxicology was forced to make a Corrigendum two years later: "*When this article was originally published on 28th September 2016, the contributions, contractual status and potential competing interests of all authors and non-author contributors were not fully disclosed to Critical Reviews in Toxicology. Specifically, the Acknowledgments and Declaration of Interest were not complete. After further clarification from the authors, these sections are corrected to reflect the full contributions, contractual status and, potential competing interests of all authors and non-author contributors and read as follows … This overview paper (paper) is part of a supplement, the preparation of which was coordinated by Intertek Scientific & Regulatory Consultancy (Intertek) under the leadership of Ashley Roberts. It was prepared subsequent to completion of the four manuscripts as an overview and presented the opinions and conclusions of four groups of the expert panel. The expert panels were organized and supported administratively by Intertek. Funding was provided to Intertek by Monsanto Company, which is a primary producer and marketer of glyphosate and related products. All the expert panelists other than John Acquavella and Larry D. Kier were compensated through a contract with Intertek. John Acquavella and Larry D. Kier were compensated through existing consulting contracts with Monsanto Company*" [59].

Product defense by downplaying risk seems to have been one of Monsanto's strategies [60].

The German chemical company Bayer purchased Monsanto in 2018. It is facing a magnitude of lawsuits on NHL and glyphosate exposure. So far in three lawsuits about 200 million USD have been awarded by the juries [58]. No doubt the use of glyphosate is of large economic importance both for the producers and the agriculture. In 2017 the EU Commission extended the use of glyphosate until 2022 [61].

Radiofrequency radiation

In 2011 radiofrequency electromagnetic fields (RF-EMF) in the frequency range 30 kHz–300 GHz were evaluated by IARC at WHO to be possibly carcinogenic to humans, Group 2B [62, 63]. This was based on evidence of increased risk for glioma and acoustic neuroma in human epidemiology studies on use of mobile and/or cordless phone (DECT) [64–69]. The increased cancer risk was supported by laboratory studies [70, 71].

Extremely low frequency (ELF)-EMF was in 2001 evaluated by IARC to be a possible human carcinogen, Group 2B [72]. This was the first time that non-ionizing radiation at low intensity levels can be a possible cause of cancer. It predated the IARC finding for RF-EMF by a decade.

Since then the evidence on RF-EMF carcinogenesis has strengthened based on further human studies on use of wireless phones, as reviewed [73, 74]. Also animal studies show increased cancer risk, both near field RF-EMF exposure [75–77] and far field exposure [78, 79]. Mechanistic studies show increase of reactive oxygen species (ROS) [80] as well as DNA damage [81]. These results give support to the increased cancer risk in humans and laboratory tested animals for RF radiation. In fact, RF-EMF may now be classified as a human carcinogen, Group 1 [82, 83]. However, such classification can only be made by IARC.

Of course, these well documented health hazards from RF-EMF are not well accepted by the telecom industry and its allied experts. Several methods are used to create doubt.

Studies are discredited, only partly cited, or even not cited at all [84–86]. Thereby the uniformed reader gets the wrong information on actual risks. This includes also regulatory agencies and policy makers. Even agencies aimed at setting exposure guidelines may include pro-industry and biased scientists that obscure the true risks [87, 88].

ICNIRP

The International Commission on Non-Ionizing Radiation Protection (ICNIRP) is a private non-governmental (NGO) organization registered in Munich, Germany. ICNIRP appoints its own members and is closed to transparency. It was started in 1992 with the biophysicist Michael Repacholi as the first chairman, now emeritus member. ICNIRP has published three articles with guidelines on RF-EMF exposure [86, 89, 90]. Only thermal (heating) effects from RF radiation are recognized, thereby excluding all studies showing harmful effects at lower non-thermal intensities. In contrast to ICNIRP, some other expert panels such as European Academy of Environmental Medicine [91], the Bioinitiative group [92], and the Russian Commission for Protection from Non-Ionizing Radiation [93], take into account non-thermal RF effects and suggest much lower guidelines for RF exposure.

ICNIRP has managed to get collaborative status with WHO, as discussed previously [88]. The aim is to harmonize the RF-radiation guidelines all over the world. For that purpose ICNIRP has been successful. The guidelines are set to allow very high exposure levels so that the deployment of this technology is not hampered, in favor for industry but at disadvantage to human health and environment. In fact, the ICNIRP guidelines have never been challenged by industry in peer-reviewed articles, which must be taken as a green card for acceptance by industry.

Attributable fraction

The attributable fraction (AF), sometimes also called the etiologic fraction, is the number of cases in which exposure played an etiologic role. This is the preventable fraction if exposure would not be present. In Belpomme et al. [73] we published meta-analyses for longest cumulative use of mobile phones with odds ratio (OR) and 95 % confidence interval (CI), both for total and for ipsilateral wireless phone use. Note that only the Hardell group assessed also use of cordless phones (DECT). We present here AF based on statistically significant increased risks in the meta-analyses. AF is the proportion of cases that can be attributed to the particular exposure. This is calculated as the exposed case fraction multiplied by [(OR-1)/OR].

As displayed in Table 1 the AF for glioma was calculated to 4.88%, 95% CI = 2.44–6.57%, corresponding to 211 preventable cases, 95% CI = 105–284 cases in the longest time for all cumulative use of wireless phones. Regarding ipsilateral use of the wireless phone AF was 6.03%, 95% CI = 4.51–7.12%, yielding 150 cases; 95% CI 112–177 to be preventable.

For meningioma AF = 1.75%, 95% CI = 0.39–2.73 corresponded to 39 cases, 95 % CI = 9–61 cases for ipsilateral use of the wireless phone was calculated. Calculation of AF for acoustic neuroma yielded 4.63%, 95% CI = 3.07–5.63% corresponding to 42 cases, 95% CI = 28–51 cases for ipsilateral use of the phone.

Table 1: Attributable fraction (AF) based on meta-analyses of case-controls studies on use of wireless phones with statistically significant increased risk. For details see Belpomme et al. [73]. Odds ratio (OR), 95% confidence interval (CI), and numbers (n) are given.

	Cases		Meta-analysis		AF		AF, corresponding cases

Rates of brain tumors in the Swedish National Inpatient Register ICD-code D43

Rates of brain tumors of unknown type, D43, were studied using the Swedish Inpatient Register (IPR) without any personal identification information [94]. It was established in 1964 and has complete national coverage since 1987 [95]. Register data on D43 are available from 1998. Currently more than 99% of hospital discharges are registered. For outpatients the data are less reliable due to missing information. The reporting of outpatients has increased during more recent years so these time trends may give spurious results, thus we omitted outpatients from the analysis.

Data were analyzed for the time period 1998–2019. Age-standardized rates are not available in the register. Instead numbers of patients per 100,000 inhabitants are reported. The Joinpoint Regression Analysis program version 4.1.1.1 was used to examine numbers of patients per 100,000 in inpatient care and incidence per 100,000 person-years in the Swedish Inpatient Register, by fitting a model of 0–3 joinpoints using permutation tests with Bonferroni correction for multiple testing to calculate the number of joinpoints that best fits the material [96]. When joinpoints were detected annual percentage changes (APC) and 95% CIs were calculated for each linear segment. Average annual percentage changes (AAPC) were also calculated for the whole time period using the average of the APCs weighted by the length of the segment. To be able to calculate APC and AAPC the data was log-transformed prior to analysis. Thus, it was not possible to perform joinpoint regression analysis when there were years with no cases during that time period. Since the data do not include any personal identification no ethical approval was needed.

In men AAPC increased during 1998–2019 with +1.77%, 95% confidence interval (CI) −0.02, +3.58%, Table 2; Figure 1. The increase was highest in the age group 20–39 years, +2.90%, 95% CI +1.66, +4.16 %, Figure 2. AAPC increased statistically significant in all age groups, except 0–19 years.

Similar results were found in women with AAPC +1.70%, 95% CI +0.38, +3.05% during 1998–2019, Table 3; Figure 3. Also in women the highest increase of AAPC was found in the age group 20–39 years, +2.89%, 95% CI + 1.54, +4.27%, Figure 4. AAPC increased statistically significant in all age groups except 0–19 years and 80+ years. Especially high increase of APC was seen in women aged 60–79 years during 2005–2019, and women aged 80+ years during 2010–2019.

Table 2: Joinpoint regression analysis of brain tumor rates (numbers per 100,000) in men in the Swedish Inpatient Register 1998–2019, ICD-10 code D43 (https://sdb.socialstyrelsen.se/if_par/val.aspx).

ICD-10	Joinpoint location	APC 1 (95% CI)	APC 2 (95% CI)	APC 3 (95% CI)	AAPC (95% CI)
D43					
All men (n=10,540)	2008; 2011	+0.13 (−0.85, +1.12)	+8.95 (−3.99, +23.64)	+1.22 (−0.16, +2.63)	+1.77 (−0.02, +3.58)
0–19 years (n=662)	No joinpoint detected	–	–	–	+1.83 (−0.13, +3.82
20–39 years (n=1,117)	No joinpoint detected	–	–	–	+2.90 (+1.66, +4.16)
40–59 years (n=2,799)	No joinpoint detected	–	–	–	+1.61 (+0.88, +2.36)
60–79 years (n=4,867)	No joinpoint detected	–	–	–	+1.67 (+0.99, +2.36)
80+ years (n=1,095)	No joinpoint detected	–	–	–	+1.40 (+0.11, +2.70)

APC, annual percentage change (APC 1, time from 1998 to first joinpoint; APC 2, time from first joinpoint to 2019 or to second joinpoint; APC 3, time from second joinpoint to 2019); AAPC, average annual percentage change

Discussion

No doubt there are historical examples of late lessons from early warnings on health risks whereby preventive measurements have been neglected. Some of the examples here clearly show that if the scientific evidence on cancer risks had been taken seriously lives could have been saved.

Tobacco is a good example of cancer risks that were disregarded for decades since clear evidence of increased risk. It was not until 1986 that IARC classified tobacco as a human carcinogen, Group 1 [25]. The strategies by the tobacco industry to sow doubt on the risks include e.g., to fund research that supports their position, to hide their involvement, to promote ‘no risk’ studies, to criticize research that shows risk, and to disseminate data and their interpretation of the results to the press and layman, for further details see Bero [98].

In fact, these strategies by the tobacco industry to obscure scientific facts seem to be textbook examples on product defense that may be used by different industries.

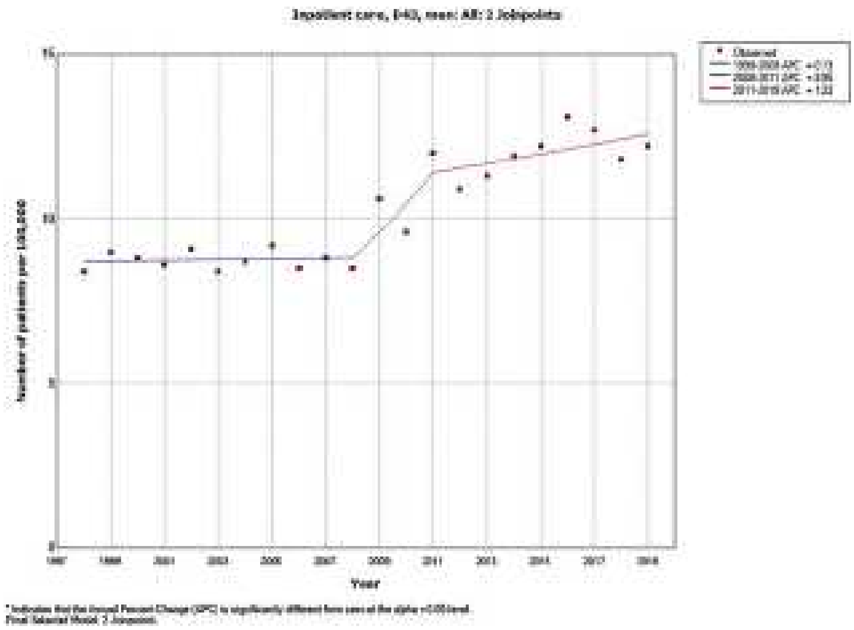

Figure 1: Joinpoint regression analysis of number of patients per 100,000 inhabitants. According to the Swedish National Inpatient Register for men, all ages during 1998–2019 diagnosed with D43 = tumour of unknown type in the brain or CNS. Note that in Sweden 1G (NMT, Nordic mobile telephone System) operated during 1981–2007. 2G (GSM) started 1991, 3G UMTS) started 2003, 4G started 2015, and DECT started 1988 [97].

One current controversy is cancer risks from RF radiation. No lessons on prevention of cancer risks seem to have been learned in spite of decades of publications on adverse health risks. In fact, early prevention is usually very cost effective [2, 99]. The issue on RF radiation risks is on-going and in fact increasing despite decades of research showing adverse effects on human health, plants, insects and birds. It seems as if the industry view of no risk dominates on national level [84], among many countries [85], also at EU level (www.5gappeal.eu), and even within WHO [88]. Notably such industry organizations and nations have the power and economic resources to suppress scientific evidence on risks and have access to mainstream media to propagate their views, may it be for political or economic reasons.

RF radiation is a current controversy regarding cancer risks. The 2011 IARC evaluation on carcinogenesis [62, 63] has been downplayed and detracted by industry and captured agencies from the very beginning in spite of increasing evidence on harmful effects. However, IARC has decided that a new evaluation of cancer risks is top priority within a few years [100].

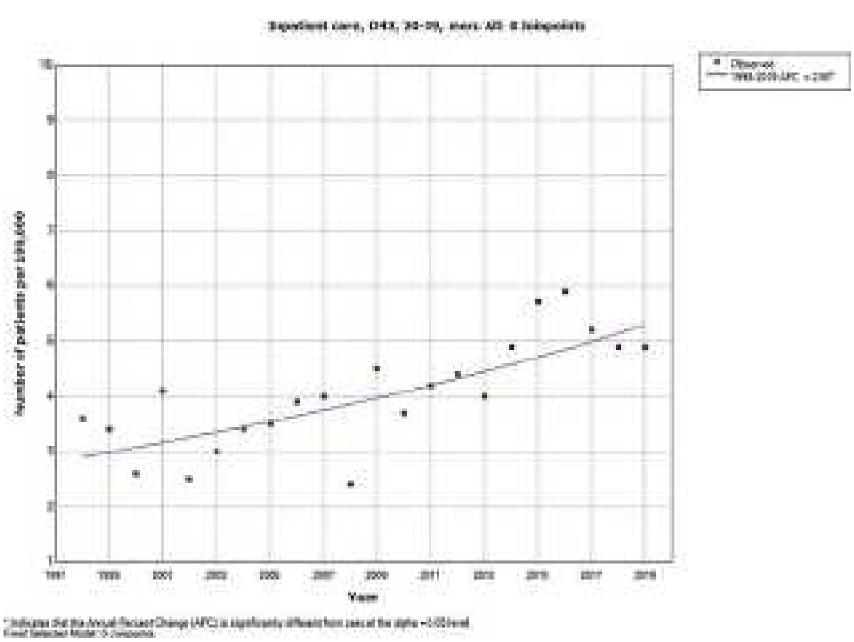

Figure 2: Joinpoint regression analysis of number of patients per 100,000 inhabitants. According to the Swedish National Inpatient Register for men aged 20–39 years during 1998–2019 diagnosed with D43 = tumour of unknown type in the brain or CNS.

Table 3: Joinpoint regression analysis of brain tumour rates (numbers per 100,000) in women in the Swedish Inpatient Register 1998–2019, ICD-10 code D43 (https://sdb.socialstyrelsen.se/if_par/val.aspx).

ICD-10	Joinpoint location	APC 1 (95% CI)	APC 2 (95% CI)	APC 3 (95 % CI)	AAPC (95% CI)
D43					
All women (n=9,611)	2008; 2017	+0.24 (−0.75, +1.24)	+4.77 (+3.32, +6.24)	−4.35 (−15.82, +8.68)	+1.70 (+0.38, +3.05)
0–19 years (n=570)	No joinpoint detected	–	–	–	+0.86 (−0.55, +2.28
20–39 years (n=907)	No joinpoint detected	–	–	–	+2.89 (+1.54, +4.27)
40–59 years (n=2,509)	No joinpoint detected	–	–	–	+1.91 (+0.80, +3.02)
60–79 years (n=4,307)	2005	−0.95 (−4.07, +2.27)	+3.45 (+2.30, +4.62)	–	+1.96 (+0,73, +3.21)
80+ years (n=1,318)	2010	−0.66 (−3.11, +1.84)	+5.49 (+1.51, +9.63)	–	+1.93 (−0.11, +4.02)

APC, annual percentage change (APC 1, time from 1998 to first joinpoint; APC 2, time from first joinpoint to 2019 or to second joinpoint; APC 3, time from second joinpoint to 2019); AAPC, average annual percentage change.

In this article we give some further data on the RF carcinogenesis. The attributable fraction gives the number of cases that could have been prevented if no risk exists for a specific exposure. Based on results in case-control studies from three study groups that have shown statistically significant increased risk for glioma and acoustic neuroma 211 glioma cases (all exposure) and 42 acoustic neuroma cases (ipsilateral exposure) would have been preventable in the longest cumulative exposure group. The preventable fraction was 4.88 and 4.63%, respectively. Highest preventable fraction was found for glioma with ipsilateral wireless phone use, 6.03% corresponding to 150 cases. Lower AF was calculated for meningioma, 1.75%, yielding 39 preventable cases (ipsilateral exposure). As displayed in Belpomme et al. [73] these results were based on Interphone [67], Coureau et al. [101], and Carlberg, Hardell [102], each without statistically significant increased risk. However, meta-analysis of these studies yielded, OR = 1.49, 95% CI = 1.08–2.06.

We have previously published results on increasing rates of tumors of unknown type in the brain or CNS both in the Swedish Inpatient Register and Causes of Death Register during 1998–2013 [103]. There was a clear increasing trend in both genders during that time period, especially during more recent years with AAPC +1.78 %, 95% CI + 0.76, 2.81% for both genders combined. A joinpoint was found in men in 2007; time period 2007–2013 APC +4.95%, 95% CI +1.59, +8.42%. Similarly, in women a joinpoint was detected in 2008; time period 2008–2013 APC +4.08%, 95% CI +1.80, +6.41%.

We have now extended the time period up to 2019. Thus, we report increasing AAPC in both genders during 1998–2019 of similar magnitude as previously. In men the result was of borderline significance although the AAPC

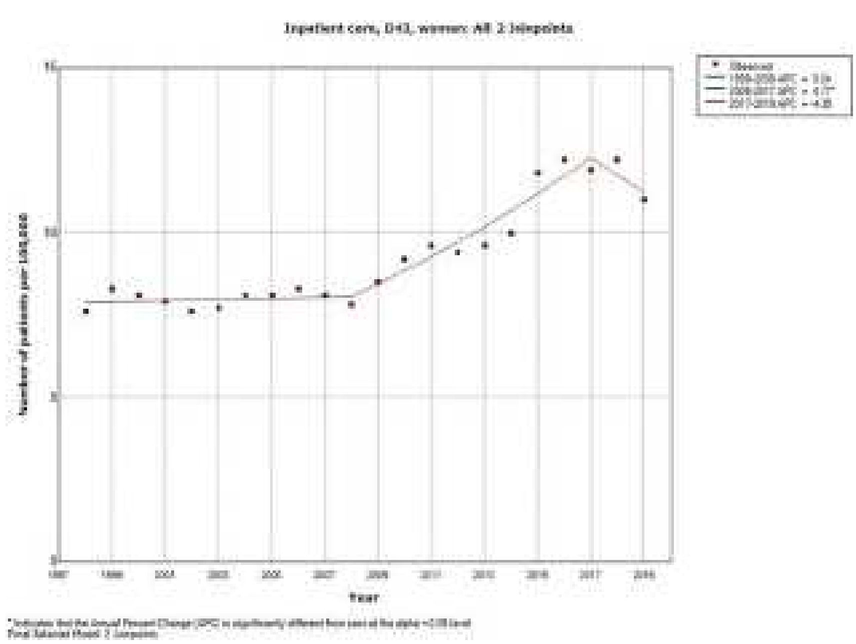

Figure 3: Joinpoint regression analysis of number of patients per 100,000 inhabitants. According to the Swedish National Inpatient Register for women, all ages during 1998–2019 diagnosed with D43 = tumour of unknown type in the brain or CNS. Note that in Sweden 1G (NMT; Nordic mobile telephone System) operated during 1981–2007. 2G (GSM) started 1991, 3G (UMTS) started 2003, 4G started 2015, and DECT started 1988 [97].

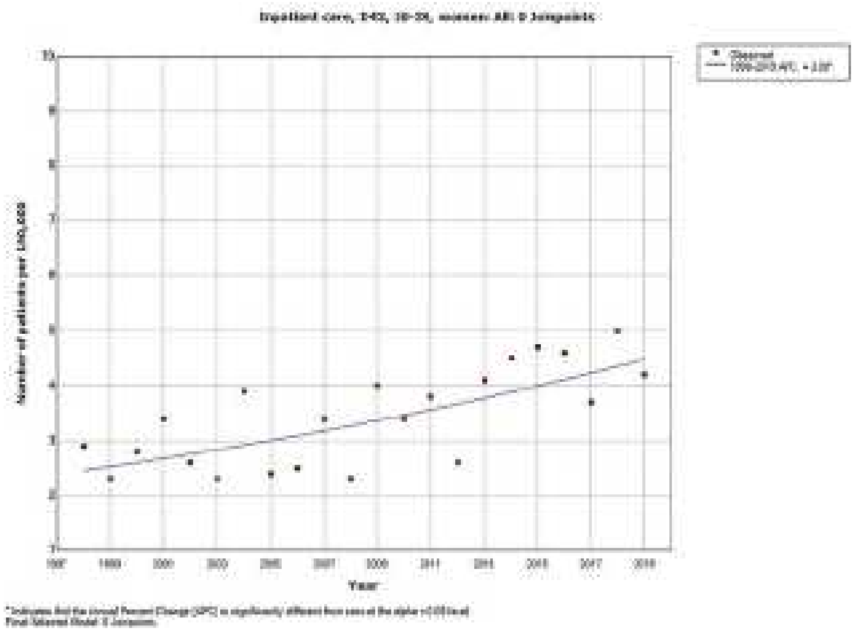

Figure 4: Joinpoint regression analysis of number of patients per 100,000 inhabitants. According to the Swedish National Inpatient Register for women aged 20–39 years during 1998–2019 diagnosed with D43 = tumour of unknown type in the brain or CNS.

overlapped previous findings. Lower APC was found during more recent years in both men and women, see Figures 1 and 3. This may reflect a better diagnostic procedure and thus decreasing numbers of unknown brain tumor type. A delay in reporting to the register during recent years may also have an impact on the results.

It is noteworthy that we found highest AAPC in the age group 20–39 years in both men and women, Tables 2 and 3. We found in our case-control study on glioma a median latency period for use of mobile phone of 9.0 years (mean 10.1 years). The corresponding results for cordless phones (DECT) were 7.0 and 8.0 years, respectively [104]. In a population-based study during 2005–2006 on use of mobile and cordless phones among Swedish children aged 7–14 years 79.1% reported access to mobile phone and use of cordless phone was reported by 83.8% [105]. Thus, our current findings with increasing numbers of brain tumors in the age group 20–39 years may be consistent with use of wireless phones taking a reasonable latency period. Moreover, our previous results showed highest risk for subjects that started the use of mobile or cordless phone before 20 years of age [104]. That age groups would also be more vulnerable to RF radiation [106]. In legends to Figures 1 and 3 we report the history for wireless phone use in Sweden. Figure 5 displays the number of out-going mobile phone minutes in millions during 2000–2019 in

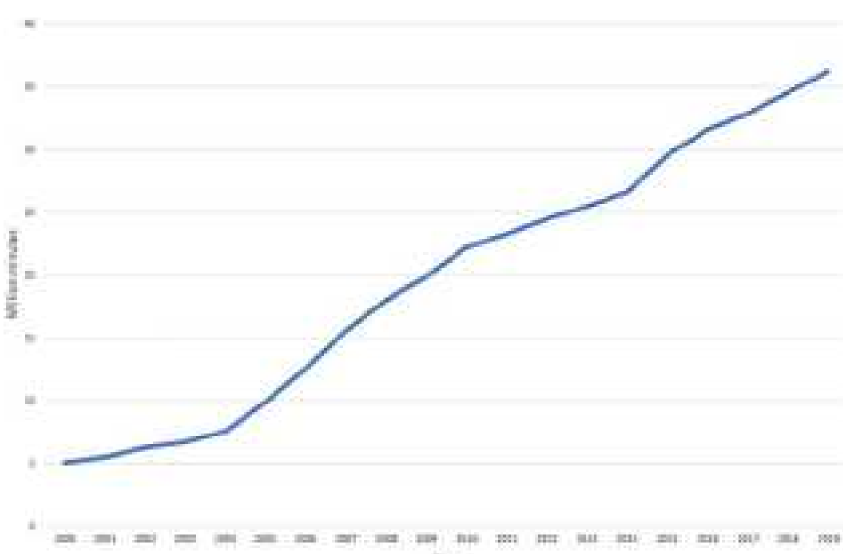

Figure 5: Number of out-going mobile phone minutes in millions during 2000–2019 in Sweden according to post-och Tele-styrelsen [The Swedish post and telecom Authority (PTS)]. Available from: https://statistik.pts.se/svensk-telekommarknad/tabeller/mobila-samtals-och-datatjanster/tabell-13-trafikminuter-utgaende/.

Sweden. The major increase is since early 21st century and may be associated with our findings of increasing numbers of brain tumors of unknown type considering a reasonable latency time.

As we have discussed elsewhere the Swedish Cancer Register is not reliable to study the incidence of brain tumors [103, 107]. The register is mainly based on reporting of cases with histopathological diagnosis. Now diagnosis may be based on CT and/or MRI without further investigations especially of patients with poor outcome. Biopsy or operation may be difficult to perform due to tumor location, age and co-morbidity. In the Swedish Cancer Register about 90% of the cases are diagnosed with cytology or histology, a number that has increased somewhat during recent years [107]. This fact indicates that brain tumors of unknown type are under-reported to the Cancer Register.

This review gives insight into missed opportunities for cancer prevention exemplified by asbestos, tobacco, certain pesticides and now RF radiation. No doubt economic considerations are favored instead of cancer prevention. The cancer victim is the loser in terms of suffering, life quality and shorter life expectancy. Also the life for the next-of-kin is affected. A strategy to sow doubt on cancer risks was established decades ago and is now adopted and implemented in more sophisticated way by the telecom industry regarding RF-EMF risks to human beings and the environment. Industry has the economic power, access to politicians and media whereas concerned people are unheard.

Abstract

Currently the fifth generation, 5G, for wireless communication is about to be rolled out worldwide. Many persons are concerned about potential health risks from radiofrequency radiation. In September 2017, a letter was sent to the European Union asking for a moratorium on the deployment until scientific evaluation has been made on potential health risks (http://www.5Gappeal.eu). This appeal has had little success. The Health Council of the Netherlands released on September 2, 2020 their evaluation on 5G and health. It was largely based on a World Health Organization draft and report by the Swedish Radiation Safety Authority, both criticized for not being impartial. The guidelines by the International Commission on Non-Ionizing Radiation Protection were recommended to be used, although they have been considered to be insufficient to protect against health hazards (http://www.emfscientist.org). The Health Council Committee recommended not to use the 26 GHz frequency band until health risks have been studied. For lower frequencies, the International Commission on Non-Ionizing Radiation Protection guidelines were recommended. The conclusion that there is no reason to stop the use of lower frequencies for 5G is not justified by current evidence on cancer risks as commented in this article. A moratorium is urgently needed on the implementation of 5G for wireless communication.

Key Words: 5G; Cancer risk; Health Council Netherlands

Core Tip: In this comment, guidelines for radiofrequency radiation are discussed in

Grade E (Poor): 0

relation to a recent evaluation by the Health Council of the Netherlands. The Committee recommends that for the deployment of 5G the frequency band 26 GHz should not be used. For lower frequencies, the International Commission on Non-Ionizing Radiation Protection guidelines are recommended. However, these guidelines are not based on an objective evaluation of health risks, which is discussed in this paper.

INTRODUCTION

The fifth generation, 5G, for wireless communication is about to be rolled out worldwide in spite of health concerns. This has created debate among concerned people in many countries. In an appeal to the European Union (EU) in September 2017, currently endorsed by more than 400 scientists and medical doctors, a moratorium on the 5G deployment was required until proper scientific evaluation of negative consequences has been made (http://www.5Gappeal.eu). This has not had any impact on the progress of the deployment of 5G.

On September 2, 2020, the Health Council of the Netherlands released their evaluation of 5G and health (No. 2020/16/16e/16Ae). The Committee consists of 9 members, 2 scientific secretaries, 1 incidentally consulting expert, and 3 observers. (https://www.healthcouncil.nl/documents/advisory-reports/2020/09/02/5g-and-health).

Of large concern as to impartiality is that one member of the Committee, Huss A, is a member of the International Commission on Non-Ionizing Radiation Protection (ICNIRP) since May 2020. ICNIRP is a private organization based in Germany that does not acknowledge health effects other than caused by heating from radiofrequency (RF) radiation. Thereby nonthermal biological effects are disregarded.

Furthermore, one of the two secretaries, van Rongen E, has been a long-time commission member of ICNIRP since 2010, chair 2016 to 2020, and vice chair since May 2020 (https://www.researchgate.net/profile/Eric_Rongen). A third former ICNIRP member, Sienkiewicz Z, participated as a consulting expert.

It should be added that Huss A receives research funding from a telecom industry sponsored Swiss Foundation, and she is also member of this foundation's Scientific Committee (https://www.emf.ethz.ch/en/foundation/organisation). Further, van Rongen E is a long-time member of the industry organizations, the Institute of Electrical and Electronics Engineers and the International Committee on Electromagnetic Safety (IEEE/ICES).

These facts give concern of conflicts of interest in the Health Council Committee. Members of ICNIRP tend to adhere also in other settings to the ICNIRP no-risk paradigm regarding nonthermal RF radiation. This may also be the case in the Health Council report. In fact it should be noted that the Ethical Board at the Karolinska Institute in Stockholm, Sweden concluded already in 2008 that being a member of ICNIRP may be a conflict of interest that should be stated officially whenever a member from ICNIRP makes opinions on health risks from electromagnetic fields (EMFs) on behalf of another organization, as in this case (Karolinska Institute Diary No. 3753-2008-609). This verdict is related to Prof. Ahlbom A, ICNIRP Commission Member from 1996 until 2008, and is a general statement. Those involved in the current Health Council report with ICNIRP affiliation (present or former) omitted to state that conflict of interest.

Recommendations by the Health Council of the Netherlands

The Committee has made four recommendations to the Parliament, cited in the following: (1) Because the lower frequency bands for 5G (up to 3.5 GHz) have already been used for telecommunication applications and Wi-Fi for years without resulting in any proven adverse health effects, the committee sees no reason to stop or restrict the use of these frequency bands. It does, however, recommend that the exposure should be monitored before, during and after the rollout of the 5G systems. This will make clear to what extent exposure to radiofrequency EMF changes as a result of the introduction of 5G, and any long-term health risks can then be estimated better. The World Health Organization (WHO) analysis can also be used in estimating the risks; (2) The committee recommends doing more research: epidemiological research into the relationship between exposure to the 5G frequencies used and the incidence of cancer, reduced male fertility, poor pregnancy outcomes and birth defects. An ongoing international study into the use of mobile telephones, in which the Netherlands is participating, can play a role in this: (a) experimental research into the health effects of exposure to EMFs in the 26 GHz frequency band; (b) scenario studies to get a picture of the exposure of individuals as a result of wireless communication systems (3G, 4G and 5G); (3) The committee recommends to not use the 26 GHz frequency band for 5G for as long as the potential health risks have not been investigated; and (4) Finally, the committee recommends using the latest guidelines from the ICNIRP as the basis for exposure policy in the Netherlands. Because it cannot be excluded that exposure under the latest ICNIRP standards also has the potential to affect health, the committee recommends taking a cautious approach and keep exposures as low as reasonably achievable.

Of these conclusions, number 3 is in agreement with an appeal to the EU asking for a moratorium on the roll-out of 5G until research has been done on potential health risks, although the appeal concerned all 5G frequencies (https://www.5gappeal.eu). The appeal has currently been signed by more than 400 international scientists and/or medical doctors.

The claim that "the lower frequency bands for 5G (up to 3.5 GHz) have already been used for telecommunications applications and Wi-Fi for years without resulting in any proven adverse health effects" is incorrect.

Evidence from research on cells, animals and humans shows that the frequencies used so far for telecommunications are harmful for humans and the environment. For overviews see[1-3].

There is no substantial research on health effects from the frequencies in the range between 3 and 4 GHz intended to be used for 5G as noted by the French authority ANSES in an expert report published in January 2020.

The Health Council Committee in Netherlands has mainly based its review on a 2014 draft report from the WHO and the reports from the Swedish Radiation Safety Authority (SSM). Huss A and van Rongen E have been coauthors of the Swedish SSM reports, and van Rongen E was furthermore a member of the WHO draft report's core group of members, see Table 1.

The Committee recommends using the latest ICNIRP 2020 guidelines, which in turn relies on the 2014 draft report from the WHO, the reports from the SSM and the 2015 report from the Scientific Committee on Emerging and Newly Identified Health Risk (SCENIHR).

There seems to be an "ICNIRP cartel" of experts that dominate different expert evaluations, *e.g.,* ICNIRP, WHO, SSM, SCENIHR. This seems also to be the case in this Health Council report, see Table 1.

As a general rule, scientists who are of the opposing opinion, *i.e.*, that there are health risks associated with exposure to RF radiation, have never been invited to take part of these expert groups. Thus, the opinions expressed in these reports are not representative of the opinions in the scientific community on effects from EMFs (https://www.emfscientist.org).

It is pertinent to evaluate the current ICNIRP 2020 conclusions on cancer risks from RF radiation because the Health Council of the Netherlands recommends using the ICNIRP 2020 guidelines. The recommendation to "take a cautious approach and keep exposures as low as reasonably achievable" is certainly difficult to achieve on a market with expanding wireless communication and may be of no practical use. It is assumed that the ICNIRP 2020 guidelines will be used in most countries. Thus, the influence by ICNIRP and its members on reports that form the basis for guidelines by different organizations is necessary to elucidate.

The ICNIRP

In the following, the evaluation of increased cancer risks according to ICNIRP 2020 is discussed in more detail. It should be mentioned that ICNIRP relies only on thermal (heating) effects from RF radiation. Nonthermal effects are dismissed thereby neglecting a large amount of scientific evidence on harmful nonthermal effects, for instance DNA damage[4], oxidative stress[5] and cancer[2]. It should be noted that the International Agency for Research on Cancer (IARC) at the WHO evaluation from 2011 is not included in the report. IARC concluded that RF radiation in the frequency range

30 kHz to 300 GHz is a possible human carcinogen, Group 2B after an evaluation by 30 international experts[6,7].

ICNIRP is a non-governmental organization based in Germany. It has obtained major influence worldwide on health risks from RF radiation through its recommended guidelines for limiting RF radiation exposure published in 1998, 2009 and 2020[8-10].

ICNIRP maintains the same attitude towards health effects from RF radiation as the IEEE and its standards setting Committee, the ICES. In fact, several members of ICNIRP are also members of these organizations, for instance van Rongen E, member of ICES since 2000. ICES is dominated by industry and military representatives[11]. ICES within IEEE also sets limits for RF exposure, which are in line with the ICNIRP's opinion that there are only immediate thermal effects, and no effects below those that cause immediate effects due to increased temperature.

As stated in an EU report[12], ICNIRP's chairman, van Rongen E, was invited in 2016 to the industry organization ICES to comment and thereby influence the upcoming ICNIRP 2020 guidelines. The report concluded that it is "clear from ICES minutes that ICNIRP worked very closely with IEEE/ICES on the creation of the new RF safety guidelines that were published in March 2020. And this implies that large telecom-companies such as Motorola and others, as well as United States military, had a direct influence on the ICNIRP guidelines, which are still the basis for EU- policies in this domain."

This adds to the evidence that van Rongen E, one of two secretaries of this Health Council, seems to have conflicts of interest.

In 2020, ICNIRP published new guidelines on health risks[10]. These updated guidelines were based on documents from the WHO, the SSM and the SCENIHR, as mentioned earlier, without any new thorough evaluation of its own.

Not one of these three reviews has been published after peer review in a scientific journal. In fact, substantial critique from the scientific community has been expressed against these reviews but has been ignored[13,14]. It should be noted that the most recent research is not covered in these older documents.

WHO

A draft of a monograph on health effects of EMF exposure was released by the WHO in 2014 but has never been published as a final version[15]. Public consultations were open until December 31, 2014.

It should be noted that the WHO in 2014 issued the following statement: "This is a draft document for public consultation. Please do not quote or cite"[15]. Nevertheless, this WHO draft from 2014, issued by a group dominated by ICNIRP members, among them van Rongen E, was used as a basis for the ICNIRP guidelines 2020 and this new report by the Health Council of the Netherlands. Five of six members of the WHO core group were members of ICNIRP, see Table 1[16]. The WHO group was nearly identical to ICNIRP.

The SCENIHR

The following quote is from the SCENIHR report 2015[17]: "Overall, the epidemiological studies on mobile phone RF EMF exposure do not show an increased risk of brain tumors. Furthermore, they do not indicate an increased risk for other cancers of the head and neck region…The results of cohort and incidence time trend studies do not support an increased risk for glioma while the possibility of an association with acoustic neuroma remains open."

The SCENIHR report was criticized for its biased presentation and conclusions[13,14]. Like the WHO draft report and the Swedish reports by SSM, it was written by a group of experts with no representation from the many scientists that report increasing evidence of harmful effects below the ICNIRP guidelines and demand better protection against health risks (https://www.emfscientist.org). SCENIHR included scientists with financial ties to industry or membership in ICNIRP or IEEE.

The SSM

Between 2003 and 2019, the SSM group has published reports in English on its webpage, three cited by ICNIRP 2020[18-20]. In line with ICNIRP, the SSM reports have ignored harmful effects from nonthermal RF exposure. Since the first report in 2003 until today, around half of the group's members have also been present or previous ICNIRP members. Both van Rongen E and Huss A have been part of this group of SSM experts. In consequence, the conclusions have generally been that there are no health risks below the limits recommended by themselves, *i.e.* in agreement with ICNIRP.

The 2018 annual report was the twelfth in this series and covered studies published from October 2015 up to and including March 2017. The conclusion was that "No new health risks have been identified"[20].

It should be noted that SSM in April 2020 published a new report from the SSM expert group that concluded: "The results of the research review give no reason to change any reference levels (ICNIRP's) or recommendations in the field." Of the ten members in the scientific group, five were present or past members of ICNIRP[21].

Current ICNIRP evaluation

van Rongen E, at that time chair of the ICNIRP Commission, claimed in a press release of the new ICNIRP 2020 guidelines that the 1998 version was "conservative in most cases" and "still provide adequate protection for current technologies." He also argued that "The most important thing for people to remember is that 5G technologies will not be able to cause harm when these new guidelines are adhered to"[22]. Because there is still no published peer-reviewed research showing no health effects from the new 5G technology, not even from short-term exposure, that is a statement without scientific foundation.

Many incorrect statements were made in the ICNIRP 2020 article[10]. In the following, the section on cancer is commented. That section starts at page 41 in the ICNIRP 2020 article with "There is a large body of literature concerning cellular and molecular processes that are of particular relevance to cancer. This includes studies of cell proliferation, differentiation and apoptosis-related processes, proto-oncogene expression, genotoxicity, increased oxidative stress, and DNA strand breaks. Although there are reports of effects of radiofrequency EMFs on a number of these endpoints, there is no substantiated evidence of health-relevant effects."

Regarding studies on cancer risks, no current evaluation is made. Several studies are not included, or references are not even given to the discussed studies. This is not easily understood by the reader that is not experienced in this area.

Regarding animal studies yielding a tumor promoting effect from RF radiation[23,24], ICNIRP states that "interpretation of these results and their applicability to human health (is) difficult, and, therefore, there is a need for further research to better understand these results." In the next paragraph, the recent animal National Toxicology Program (NTP) studies[25,26] and Ramazzini Institute results[27] on animal carcinogenesis from RF radiation are disregarded stating that "no consistency was seen across these two studies" and "within the context of other animal and human carcinogenicity research (HCN 2014, 2016), their findings do not provide evidence that radiofrequency EMFs are carcinogenic."

That is a remarkable statement with no risk by ICNIRP and is not based on what the science really showed. There is a pattern of increased cancer risk based on human epidemiology, animal research and experimental findings. The Hardell team concluded that "There is clear evidence that RF radiation causes cancer/tumor at multiple sites, primarily in the brain (glioma) and head (acoustic neuroma). There is also evidence of an increased risk of developing other tumor types. The results are similar in both the NTP studies and the Ramazzini Institute findings (Falcioni *et al* [27]). Based on the IARC preamble to the monographs, RF radiation should be classified as Group 1: The agent is carcinogenic to humans"[28].

In a note published by ICNIRP, it was claimed that the histopathological evaluation in the NTP study was not blinded as to exposure status[29]. This false accusation was rebutted by one of those responsible for the NTP study[30]. However, the rebuttal seems to have had no impact on the current ICNIRP evaluation[10].

Regarding the 13 country Interphone case-control study on glioma[31] and acoustic neuroma[32], ICNIRP concluded that the studies do "not provide evidence of an increased risk," which is not correct. However, regarding glioma cumulative call-time of mobile phone ≥ 1640 h yielded odds ratio (OR) = 1.40, 95% confidence interval (CI) = 1.03-1.89. The risk increased over time for exposure and was highest in the most exposed parts of the brain. These findings were of biological relevance.

RF radiation dose was estimated in parts of Interphone as total cumulative specific energy (J/kg) absorbed at the tumor's estimated center taking into account multiple RF exposure determinants[33]. The risk increased with increasing total cumulative specific energy 7+ years before diagnosis, OR = 1.91, 95%CI = 1.05-3.47 (*P* value = 0.01) in the highest quintile. Compared with glioma in other parts of the brain increased, ORs were found for tumors in the most exposed part of the brain in those with 10+ years of mobile phone use, OR = 2.80, 95%CI = 1.13-6.94.

Grell *et al*[34] published similar results for the Interphone study. "We found a statistically significant association between the intracranial distribution of gliomas and the self-reported location of the phone…Taken together, our results suggest that ever using a mobile phone regularly is associated with glioma localization in the sense that more gliomas occurred closer to the ear on the side of the head where the mobile phone was reported to have been used the most."

For glioma, when comparing those in the highest quartile of use (> 558 lifetime hours) to those who were not regular users, the OR was 2.0, 95%CI = 1.2-3.4 in the Canadian part of Interphone[35]. After adjustment for selection and recall biases, a somewhat higher OR was found, 2.2, 95%CI = 1.3-4.1.

The Interphone study gave for acoustic neuroma statistically significant increased risk. Thus, ipsilateral cumulative mobile phone use > 1640 h gave OR = 2.33, 95%CI = 1.23-4.40[32].

Regarding the Hardell team studies, ICNIRP writes: "a set of case-control studies from the Hardell group in Sweden report significantly increased risks of both acoustic neuroma and malignant brain tumors already after less than five years since the start of mobile phone use, and at quite low levels of cumulative call time." The studies are not carefully evaluated by ICNIRP and no references are given. On the contrary, overall there was no statistically increased risk in the shortest latency period > 1-5 years for glioma or acoustic neuroma[36,37]. Somewhat higher risk was seen for ipsilateral exposure; a promotor effect cannot be excluded in addition to initiation of cancer[36]. Also in the Hardell team studies the risk increased with latency and cumulative use and was highest in the most exposed areas of the brain that would be expected for carcinogenesis. Concepts of both promotion, initiation and biological relevance for RF radiation carcinogenesis must be considered when discussing results in different studies. That is obviously not the case for ICNIRP.

In addition, ICNIRP claims that the Hardell team results may be caused by recall bias. For meningioma, no statistically significant increased risk was found in the same study. Using meningioma cases as "controls" (the comparison entity) still yielded statistically significant increased risk for glioma and mobile phone use[36]. Similar results were found for acoustic neuroma using meningioma cases as the comparison group[37]. These results clearly show that the increased risks for glioma and acoustic neuroma were not caused by recall bias, *i.e.* cases tending to overestimate exposure. That would have applied to all cases regardless of tumor type.

ICNIRP omitted the CERENAT study by Coureau *et al*[38]. The study strengthened the evidence of increased risk for glioma associated with mobile phone use. Life-long cumulative duration ≥ 896 h gave OR = 2.89, 95%CI = 1.41-5.93 for glioma. Number of calls ≥ 18360 gave OR = 2.10, 95%CI = 1.03-4.31. Higher risks were obtained for the highest exposed area, the temporal brain lobe, as well as occupational and urban mobile phone use.

In spite of serious methodological limitations, the Danish cohort study on mobile phone use was included, adding to the ICNIRP no-risk conclusion. This study, partly funded by Danish telecom operators, first published in 2001[39] and updated in 2011 [40], reported no increased risks of tumors in the central nervous system. It was based on 420095 mobile phone private subscribers. This group's incidence of brain tumors was compared to the incidence within the rest of the Danish population (control group). However, there are several methodological limits in the study such as inclusion only of mobile phone private subscribers in Denmark between 1982 and 1995 in the exposure group. The most exposed group, corporate users, and subscription in

1996 or later were excluded. Use of cordless/DECT phones was disregarded although shown to be a risk factor for brain and head tumors[36,37].

The study has been called "The most severely biased study among all studies published so far"[41]. Certainly, there were severe methodological flaws. The Danish cohort study was regarded by IARC in the 2011 evaluation[7] to be uninformative regarding cancer risks due to serious exposure misclassification. However, it was included by SCENIHR[17], WHO[15], SSM (2013)[42], and ICNIRP[10] as evidence of no risk. The statement by SSM 2013[42] that "The Danish cohort studies make an important contribution to the total assessment in the field" is not correct. The shortcomings in the study should have been known to the SSM expert panel as discussed in a peer-reviewed article[43] concluding that "After reviewing the four publications on the Danish cohort study, one might rightly wonder whether this cohort was initially set up to show no increased risk."

The ICNIRP 2020[10] reference levels for RF radiation are based on time averaged exposure over 6 min or 30 min. However, pulses from different RF radiation sources may give much higher peak radiation from short time pulses than the power density average. Using time averaging in reference values may thus underestimate the risk. In addition, ICNIRP 2020 suggests higher guidelines for local exposure. According to the article, the reference level, *e.g.*, > 2 to 6 GHz local exposure, is suggested to increase to 40 W/m^2 time averaged over 6 min. This is contrary to the increasing scientific evidence on detrimental effects on human health and the environment from RF radiation. Previously 10 W/m^2 was used as reference level time averaged 6 min exposure[8,9]. Now the reference level for whole body exposure, time averaged 30 min, is suggested to be 10 W/m^2.

The evidence for cancer

Several meta-analyses have during the last years reached the conclusions that all together the available evidence shows increased risk of cancer from mobile phone use [2]. One additional method is to use Sir Bradford Hill's viewpoints from 1965 on association or causation written at the height of the tobacco and lung cancer controversy[44]. In an article published in 2017, these viewpoints were used to evaluate RF radiation carcinogenesis based on epidemiology and laboratory studies [45]. It was concluded that based on these Hill "criteria" RF radiation should be regarded as a human carcinogen causing glioma. Since then the evidence has strengthened.

As discussed above, studies have shown an association between glioma and acoustic neuroma and mobile phone use especially in: (1) people with longest latency (time from first use until tumor diagnosis); (2) people with highest cumulative use of mobile phones; (3) people who had used mobile phones on the same side of the head as that on which their tumor developed; and (4) in people whose tumor was in the temporal lobe of the brain, *i.e.* the highest exposed lobe during use of the handheld wireless phone.

In addition, the Hardell team studies from Sweden found similar results for use of cordless phones. Thus, based on these findings that are of biological relevance and supported by the Hill viewpoints, a causal interpretation is possible. Thus, RF radiation should be classified as a human carcinogen, Group 1 according to the IARC criteria[45,46]. However, only IARC can make that classification.

DISCUSSION

In order to achieve sustainable development, policies must be based on the precautionary principle. No doubt there are threats of serious or irreversible damage by exposure to RF radiation, not the least the increased risk for glioblastoma with short survival for those affected[47]. Lack of full scientific certainty, as proposed by certain public health organizations, should not be used as a reason for postponing measures to prevent environmental degradation. Thus, a moratorium on the deployment of 5G and considerable reduction of RF radiation from existing systems is urgently needed. In short, "The precautionary principle provides justification for public policy actions in situations of scientific complexity, uncertainty and ignorance, where there may be a need to act in order to avoid, or reduce, potentially serious or irreversible threats to health or the environment, using appropriate strengths of scientific evidence, and taking into account the likely pros and cons of proportionate actions and inactions" [48].

In contrast to that as a general rule, ICNIRP, WHO, SSM, and SCENIHR have for many years dismissed available studies showing harmful effects from nonthermal RF radiation exposure and have based their conclusions mainly on studies showing no effects. Thereby results showing health hazards are criticized or not even cited in contrast to studies showing no risks that are accepted as evidence of no risk in spite of severe methodological problems. Many of the statements by these agencies are misleading and not correct. They are easily rebutted by reading the relevant publications. In fact, an Italian court ruling linked mobile phone use to tumors already in 2012. Also, later court rulings in Italy have come to the same conclusion.

These ICNIRP cartel dominated expert groups consequently reach similar conclusions that there are no health effects below ICNIRP guidelines. Scientists with opinions that there is increasing evidence of health risks below the ICNIRP guidelines, *e.g.,* as expressed in the EMF Scientists Appeal, are not invited to expert groups at the WHO, the EU (SCENIHR), the SSM, or ICNIRP. Table 1 clearly illustrates that few persons constitute different groups aimed at preventing hazards and risks to the health and the environment. The ICNIRP view is thereby influencing these expert reports, which also formed the basis for this Health Council report in the Netherlands.

There is growing scientific evidence on health risks from the RF radiation emitted by existing telecommunications systems prior to 5G. In addition, 5G will lead to an increase of radiation, including new techniques, which leads to the conclusion that hazardous exposure will increase. However, it is unacceptable that there is scanty research being performed on the risks or hazards from the new 5G technology and the new frequencies that will be used. This means an experiment on human health and the environment that should not be accepted. Thus informed consent would be needed from each involuntary exposed person. The exposure guidelines in ICNIRP 2020[10] constitute a hazard to public health and the environment because evidence is abundant on harmful effects including DNA damage, oxidative stress, and cancer.

The Health Council Committee argues that "epidemiological research into the relation between exposure to the 5G frequencies used and the incidence of cancer, reduced male fertility, poor pregnancy outcomes and birth defects" should be performed after the roll-out of the 5G and its increase in radiation. However, the same Committee in the same report claims that "The committee has however classified relations as "possible" for cancer, male fertility, pregnancy outcomes and birth defects."

Further the Committee states that "The conclusions from those earlier reports are also relevant for 5G as far as the frequency bands around 700, 1400, 1800 and 2100 MHz are concerned. The committee sees no reason to limit or stop the use of the lower frequency bands for 5G. Frequencies near 700 MHz and 3.5 GHz have been in use for current telecommunication systems or other applications such as Wi-Fi for years, without any demonstrable health damage as a result."

Thus, this report states that 5G at the lower frequencies has no "demonstrable health damage, although relations (are), "possible" for cancer, male fertility, pregnancy outcomes and birth defects".

The least to say is that the Committee is not transparent regarding health risks; they are "possible" but for the roll-out of 5G they are not "demonstrable." Research on health hazards must be done before exposure, not after, something that is suggested for the higher frequencies. "The committee recommends not to use the 26 GHz frequency band for 5G for as long as the potential health risks have not been investigated."

For implementation of 5G, regardless of frequency, ethics in medicine should be applied. In medicine the patient must be informed about the risks but also benefits in experimental studies and give written consent for the participation. That should also apply to the deployment of 5G. However, it has not been done so far. The participation is forced upon everybody, which is of course unacceptable from a human rights perspective.

CONCLUSION

In conclusion regarding cancer, current scientific evidence clearly demonstrates an increased risk for glioma and acoustic neuroma for use of mobile and/or cordless phones. In this review other tumor types and health endpoints are not discussed. The increased risk for brain and head tumors is based on human cancer epidemiology studies and is supported by similar tumor types found in animal studies. In fact, these animal studies confirmed the earlier results in case-control studies on increased tumor risk for use of wireless phones (both mobile and cordless phones). Mechanistic aspects on carcinogenesis come from laboratory findings on, *e.g.*, the increase of reactive oxygen species[5] and DNA damage[4].

The current evaluation by the Health Council of the Netherlands is based on a WHO draft and SSM report. It also recommends using ICNIRP guidelines, considered to be insufficient to protect against health hazards, such as cancer, by the majority of the scientists in this field (https://www.emfscientist.org). The report does not represent a thorough, balanced, objective, and up-to-date evaluation of cancer risks and other hazardous effects from RF radiation. It is also strikingly contradictory as it concludes that serious health effects such as cancer and birth defects are "possible." Yet it has no objection to the roll-out of 5G and recommends that later studies are performed to study health outcomes such as cancer and birth defects. Thus, no lessons are learned from existing observations on increased cancer risks[49].

The conclusion by the Commission that there is no reason to stop the use of lower frequencies for 5G up to 3.5 GHz because of no "proven adverse health effects," merely reflects the biased conclusions by ICNIRP dominated groups. Thus that conclusion must be dismissed, and new guidelines for previous and new frequencies must be established considering the new technology, the different propagation pattern for 5G, and increased RF radiation.

A moratorium is urgently required on the implementation of 5G for wireless communication[13]. Ultimately, wired solutions are preferred.

COMMENT

Appeals that matter or not on a moratorium on the deployment of the fifth generation, 5G, for microwave radiation

LENNART HARDELL[1,3] and RAINER NYBERG[2,4]

DOI: 10.3892/mco.2020.1984

Abstract. Radiofrequency (RF) radiation in the frequency range of 30 kHz-300 GHz is classified as a 'possible' human carcinogen, Group 2B, by the International Agency for Research on Cancer (IARC) since 2011. The evidence has since then been strengthened by further research; thus, RF radiation may now be classified as a human carcinogen, Group 1. In spite of this, microwave radiations are expanding with increasing personal and ambient exposure. One contributing factor is that the majority of countries rely on guidelines formulated by the International Commission on Non-Ionizing Radiation Protection (ICNIRP), a private German non-governmental organization. ICNIRP relies on the evaluation only of thermal (heating) effects from RF radiation, thereby excluding a large body of published science demonstrating the detrimental effects caused by non-thermal radiation. The fifth generation, 5G, for microwave radiation is about to be implemented worldwide in spite of no comprehensive investigations of the potential risks to human health and the environment. In an appeal sent to the EU in September, 2017 currently >260 scientists and medical doctors requested for a moratorium on the deployment of 5G until the health risks associated with this new technology have been fully investigated by industry-independent scientists. The appeal and four rebuttals to the EU over a period of >2 years, have not achieved any positive response from the EU to date. Unfortunately, decision makers seem to be uninformed or even misinformed about the risks. EU officials rely on the opinions of individuals within the ICNIRP and the Scientific Committee on Emerging and Newly Identified Health Risks (SCENIHR), most of whom have ties to the industry. They seem to dominate evaluating bodies and refute risks. It is important that these circumstances are described. In this article, the warnings on the health risks associated with RF presented in the 5G appeal and the letters to the EU Health Commissioner since September, 2017 and the authors' rebuttals are summarized. The responses from the EU seem to have thus far prioritized industry profits to the detriment of human health and the environment.

Introduction

Over the years, numerous international appeals on radiofrequency (RF) radiation and health and the environment have been published (e.g., www.emfscientist.org). These seem to have had little or no impact on those proposing limits on RF radiation and on the deployment of this technology. On the contrary, ambient RF radiation exposure has increased and is a potential health risk based on the current knowledge of the biological effects of RF radiation (1-8). There seems to be an 'unholy' alliance between the telecom industry and certain scientists, organizations (even WHO), and some politicians, thus reducing the potential for precautionary actions (9,10).

The International Agency for Research on Cancer (IARC) of WHO in 2011 classified RF radiation in the frequency range of 30 kHz-300 GHz as a 'possible' human carcinogen, Group 2B (11,12). Since then, the evidence of the adverse effects of RF radiation has strengthened based on human epidemiological (7,8,13) and animal studies (14-16). These results add scientific evidence to a previous evaluation (17). Thus, RF radiation may now be classified as a human carcinogen, Group 1. That is the strongest classification, which is the same as that for e.g., asbestos and smoking.

The IARC cancer classification seems to have had little or no impact on protecting the public against risks associated with RF exposure. A major hampering factor has been the exposure guidelines by the International Commission on Non-Ionizing Radiation Protection (ICNIRP) based only on the acute and very short-term thermal (heating) effects of RF radiation. These guidelines are used by the majority of countries worldwide. These guidelines were initially published approximately 20 years ago (18) and were updated in 2009 (19); however, no changes were made to adapt to the

Key words: appeals, microwave radiation, radiofrequency radiation, radiofrequency electromagnetic field, EMF, 5G, EU, WHO, moratorium, health risks, non-ionizing radiation guidelines

rapidly increasing evidence of the harmful effects of RF and new RF signal characteristics and exposure from new technologies. ICNIRP, with the support of the WHO (10) and the major telecom companies, has made considerable efforts to convince countries worldwide to follow their guidelines. However, with the deployment of the 5th generation of microwave radiation, 5G, even the obsolete ICNIRP guidelines may be exceeded and may become an obstacle for the deployment of 5G (20). Thus, ICNIRP is preparing new guidelines that are briefly commented on below. However, as already published (9,10), the ICNIRP guidelines may be contradictory to a vast number of existing scientific reports demonstrating the harmful effects of RF radiation (21). Furthermore, there may perhaps also be conflicts of interests in terms of ties to the industry.

ICNIRP

On July 11, 2018, the ICNIRP released a draft of the guidelines for limiting exposure to time-varying electric, magnetic and electromagnetic fields (100 kHz-300 GHz). It was open for public consultations until October 9, 2018. Appendix B was based on the assessment of the health risks based on a literature survey (https://www.icnirp.org/en/activities/public-consultation/index.html).

Of note, in the background material to the new ICNIRP guidelines, the IARC classification from 2011 of RF exposure as class 2B, 'possibly' carcinogenic to humans (11,12) was not included. Notably, one of the ICNIRP commission members, Martin Röösli (https://www.icnirp.org/en/about-icnirp/commission/index.html), was also one of the IARC experts evaluating the scientific RF carcinogenicity in May, 2011 (https://monographs.iarc.fr/wp-content/uploads/2018/06/mono102-F05.pdf), which classified RF exposure as a class 2B 'possible' carcinogen. Thus, he should be aware of the IARC classification. Of note, one of the authors of this article (L.H.) was a member of the IARC expert group.

Below, eight excerpts/quotes from the 2018 ICNIRP draft guidelines are presented (https://www.icnirp.org/cms/upload/consultation_upload/ICNIRP_RF_Guidelines_PCD_2018_07_11.pdf). These assertions in the ICNIRP evaluation do not seem to represent the valid evaluation of the published literature on the health risks associated with RF:

i) ***Brain physiology and function.*** *'In summary, there is no evidence of effects of radiofrequency EMF [electromagnetic field] on physiological processes or eye pathology that impair health in humans. Some evidence of superficial eye damage has been shown in rabbits at exposures of at least 1.4 kW m-2, although the relevance of this to humans has not been demonstrated'.*

ii) ***Auditory, vestibular, and ocular function.*** *'In summary, no effects on auditory, vestibular, or ocular function relevant to human health have been substantiated'.*

iii) ***Neuroendocrine system.*** *'In summary, the lowest level at which an effect of radiofrequency EMF on the neuroendocrine system has been observed is 4 W kg-1 (in rodents and primates), but there is no evidence that this translates to humans or is relevant to human health. No other effects have been substantiated'.*

iv) ***Neurodegenerative diseases.*** *'In summary, no adverse effects on neurodegenerative diseases have been substantiated'.*

v) ***Cardiovascular system, autonomic nervous system and thermoregulation.*** *'In summary, no effects on the cardiovascular system, autonomic nervous system, or thermoregulation that compromise health have been substantiated for exposures with whole body average SARs below approximately 1 W kg-1, and there is some evidence that 4 W kg-1 is not sufficient to alter body core temperature in hamsters. However, there is strong evidence that whole body exposures in rats that are sufficient to increase body core temperature by several degrees centigrade can cause serious adverse health effects in rats'.*

vi) ***Immune system and hematology.*** *'The few human studies have not indicated any evidence that radiofrequency EMF affects health in humans via the immune system or haematology'.*

vii) ***Fertility, reproduction and childhood development.*** *'In summary, no adverse effects of radiofrequency EMF exposure on fertility, reproduction or development relevant to human health have been substantiated'.*

viii) ***Cancer.*** *'In summary, no effects of radiofrequency EMF on cancer have been substantiated'.*

Since the ICNIRP 2018 draft guidelines excluded a large number of science-based evidence of health hazards from RF radiation, numerous rebuttals have been sent to the ICNIRP. However, it remains unknown as to whether these rebuttals have been taken into account or not.

Thus, the ICNIRP does not acknowledge the health effects caused by RF radiation. This has been rebutted by several scientists (21-24).

Details and proofs of scientific misinterpretation were outlined in a comprehensive response by Dr Martin Pall (21). He demonstrated that the denials of scientific facts concerning health risks seem to be the rule in the Health Risk Assessments of the ICNIRP 2018 Draft Guidelines. ICNIRP confirmed that Pall's response was received on October 8, 2018 (tinyurl.se/pall). As outlined above in all eight summarizing statements, the ICNIRP denies that any scientific reports exist which demonstrate harmful effects below the ICNIRP guidelines. However, as Dr Pall demonstrated, a large number of peer-reviewed studies have been published over a period of >20 years contradicting the ICNIRP evaluations. Independent peer-reviewed scientific articles (1,7,8) have demonstrated the harmful effects even far below the current public safety limits based on ICNIRP 1998 reference levels 10 W/m^2 for 2-300 GHz and 2-10 W/m^2 for 400 to 2,000 MHz (18).

The ICNIRP also seems to have disregarded previously published animal studies (14-16) on carcinogenesis. The NTP results have been discussed in a commentary (25) and clarified to that degree that they should have been considered in full. These findings supported human epidemiology results on cancer risks from RF radiation (6,26). The final new ICNIRP guidelines have yet to be published.

In fact, a hint of the ICNIRP final document may be found in a presentation by the ICNIRP chairman Eric van Rongen at a meeting held on April 17, 2019 https://www.anfr.fr/fileadmin/mediatheque/documents/expace/workshop-5G/20190417-Workshop-ANFR-ICNIRP-presentation.pdf.

van Rongen stated that there is no evidence that RF EMF causes diseases, such as cancer and that the US NTP (14-15) and Ramazzini Institute (16) studies are not convincing for carcinogenesis. ICNIRP seems still to hold the view, which is clearly beneficial to the industry, that only thermal effects exist for RF radiation and not any non-thermal effects, which have been proven in research by the majority of scientists in this field.

ICNIRP recently published a note on the NTP and Ramazzini Institute animal studies (27). Some of their incorrect statements are commented on below. The ICNIRP claims that there is no verified mechanism for RF radiation carcinogenesis, in spite of well-designed studies showing the contrary, e.g., oxidative stress (25,28) and DNA damage (25,29). The ICNIRP claims that the histopathological evaluation was not blinded in these studies; however, this is not true, as supported by the methods described in these studies. Furthermore, the ICNIRP claims that the body core temperature was increased in the NTP study (15) and suggested it to be a factor increasing cancer risk, although heat is not a known carcinogen. The ICNIRP also claims that only the Hardell group found an increased risk for acoustic neuroma although the Interphone study had similar findings (7). ICNIRP does not seem to take into account the concordance between the tumor types found in human epidemiological and animal studies. These are just a few examples.

It is noteworthy that ICNIRP repeats certain debatable statements in spite of being rebutted by Melnick (25) and should have been known to the 13 ICNIRP Commission members (https://www.icnirp.org/en/about-icnirp/commission/index.html) with their names listed at the end of the article (27). Perhaps this ICNIRP article lacks scientific authorization. As previously suggested, they seem to create doubt (30,31). Thus, one must be cautious when also interpreting other publications by the 13 Commission members.

The ICNIRP points out an important scientific problem: How incorrect data can achieve lives of their own and gain respectability and credence with inappropriate repetition. Corrections and clarifications (25), seem to have difficult time to counteract any possible errors, which is to the disadvantage of both good science and public health. Of note, President Franklin D. Roosevelt stated that *'Repetition does not transform a lie into a truth'* (https://www.azquotes.com/quote/377323).

Finland, in a new regulation, 1045/2018, dated December 15, 2018, allowed higher average radiation, 200 W, in narrow areas of 1x1 cm (1 cm^2) (please see Table 1.5, Note 3 (in Swedish): (https://www.finlex.fi/data/sdliite/liite/6943.pdf). This was probably decided in order to accommodate the steerable, beam-formed, narrow 5G fields, which will be used by most 5G equipment. The Director of the Radiation Safety Agency in Finland claims that this is no problem, as if you disperse the effect of 200 W (on 1 cm^2) upon a whole square meter it will still be within the ICNIRP guideline of 10 W/m^2 (private communication from Petteri Tiippana, 2018, please see https://www.dropbox.com/s/89cm7bmb410em8w/200W%3Am2-STUK.pdf?dl=0).

On top of the other flaws which ICNIRP members are presenting, they also suggest that only the 'mean values' of RF radiation should be measured. However, the interferences and the supra-additive effects between pulses from different RF radiation sources can lead to 'hundreds of thousands higher density' short-time pulses than the power density mean values with the guideline of 10 W/m^2. This has been well-documented in a report from the Finnish Radiation Safety Agency (32). Panagopoulos (29) has clearly demonstrated that using mean values for RF radiation may underestimate the risk. Intensity, frequency, exposure duration, polarization, pulsing and modulation are crucial parameters for the bioactivity. Puranen (32) states that the instant effect density can be much stronger than the mean values. However, the guidelines only consider the mean values.

Appeals to the EU and responses from the EU

The impact of the many international appeals on RF radiation safety, if any, is unclear. However, they will be historical documents on warnings that have been thus far ignored by the EU and the WHO. This is exemplified below.

The deployment of 5G for microwave radiation has given increasing awareness and concern among individuals regarding the risks to human health and the environment resulting in massive protests and even a moratorium in certain EU countries and US cities (https://tinyurl.se/5gstoppers). 5G uses a different technology compared with previous generations, such as 2G, 3G and 4G. In the following, our 5G appeal to EU is discussed (www.5Gappeal.eu). This has currently been signed by >260 scientists and medical doctors from a number of countries. It is still open for endorsement.

a) The 5G Appeal, September 13, 2017 and response. Below, the full text, with included links to references, is presented although it can also be found online (www.5gappeal.eu), and also at (https://www.environmentandcancer.com/5g-appeal/).

Scientists and doctors warn of potential severe health effects of 5G. *'We the undersigned scientists and doctors recommend a moratorium on the roll-out of the fifth generation, 5G, for telecommunication until potential hazards for human health and the environment have been fully investigated by scientists independent from industry. 5G will substantially increase exposure to radiofrequency electromagnetic fields (RF-EMF)* *on top of the 2G, 3G, 4G, Wi-Fi, etc. for telecommunications already in place. RF-EMF has been proven to be harmful for humans and the environment'.*

5G leads to the marked increase of mandatory exposure to wireless radiation. *'5G technology is effective only over short distance. [The range of 5G radiation is decreased due to its increased carrier frequency (up to ~100 GHz) compared to previous mobile telephony generations and other existing microwave telecommunications radiations such as Wi-Fi (up to 2.6 GHz), and according to Rayleigh's law which explains that the intensity of scattered electromagnetic radiation (Jscat) is proportional to f 4 (where f is the frequency of the radiation) when the dimensions of the scattering particles - such as the molecules of the air, of the building materials, etc. - are smaller than the wavelength (which is the case for all mobile telephony radiations): Jscat ∝ f 4 (33)]. It is poorly transmitted through solid material. Many new [base] antennas will be required and full-scale implementation will result in antennas every 10 to 12 houses in urban areas,* ***thus massively increasing mandatory exposure****'.*

'[Moreover, apart from the increase in background exposure, 5G is likely to induce significant thermal effects in addition to the already non-thermal ones, again due to its significantly higher frequency (34)]'.

'With "the ever more extensive use of wireless technologies," (35) nobody can avoid to be exposed. Because on top of the increased number of 5G-transmitters (even within housing, shops and in hospitals) according to estimates, "10 to 20 billion connections" (36) (to refrigerators, washing machines, surveillance cameras, self-driving cars and buses, etc.) will be parts of the Internet of Things. All these together can cause a substantial increase in the total, long term RF-EMF exposure to all EU citizens'.

Harmful effects of RF-EMF exposure have already been proven. *'Over 230 scientists from >40 countries [now 252 scientists from 43 nations] (37) have expressed their "serious concerns" regarding the ubiquitous and increasing exposure to EMF generated by electric and wireless devices already before the additional 5G roll-out. They refer to the fact that "numerous recent scientific publications have shown that EMFs affect living organisms at levels well below most international and national guidelines". Effects include increased cancer risk, cellular stress, increase in harmful free radicals, genetic damages, structural and functional changes of the reproductive system, learning and memory deficits, neurological disorders, and negative impacts on general well-being in humans. Damage goes well beyond the human race, as there is growing evidence of harmful effects (38) to both plants (39) and animals (40)'.*

'After the scientists' appeal was written in 2015 additional research has convincingly confirmed serious health risks from RF-EMF fields from wireless technology. The world's largest study (25 million US dollar) National Toxicology Program (NTP) (41), shows statistically significant increase in the incidence of brain and heart cancer in animals exposed to EMF [intensities] below the ICNIRP (International Commission on Non-Ionizing Radiation Protection) guidelines followed by most countries. These results support results in human epidemiological studies (17) on RF radiation and brain tumour risk. A large number of peer-reviewed scientific reports (2) demonstrate harm to human health from EMFs'.

'The International Agency for Research on Cancer (IARC), the cancer agency of the World Health Organization (WHO), in 2011 concluded that EMFs of frequencies 30 KHz - 300 GHz are possibly carcinogenic to humans (Group 2B) (12,42). However, new studies like the NTP study mentioned above and several epidemiological investigations including the latest studies on mobile phone use and brain cancer risks confirm that RF-EMF radiation is carcinogenic to humans (17)'.

'The EUROPA EM-EMF Guideline 2016 (1) states that "there is strong evidence that long-term exposure to certain EMFs is a risk factor for diseases such as certain cancers, Alzheimer's disease, and male infertility…Common EHS (electromagnetic hypersensitivity) symptoms include headaches, concentration difficulties, sleep problems, depression, lack of energy, fatigue, and flu-like symptoms"'.

'An increasing part of the European population is affected by ill health symptoms that have for many years been linked to exposure to EMF and wireless radiation in the scientific literature. The International Scientific Declaration on EHS & multiple chemical sensitivity (MCS), Brussels (43), declares that: "In view of our present scientific knowledge, we thereby stress all national and international bodies and institutions… to recognize EHS and MCS as true medical conditions which acting as sentinel diseases may create a major public health concern in years to come worldwide i.e. in all the countries implementing unrestricted use of electromagnetic field-based wireless technologies and marketed chemical substances… ***Inaction is a cost to society*** *and is not an option anymore… we unanimously acknowledge this serious hazard to public health…that major primary prevention measures are adopted and prioritized, to face this* ***worldwide pan-epidemic*** *in perspective"'.*

Precautions. *'The Precautionary Principle (44) was adopted by EU 2005 (45): "When human activities may lead to morally unacceptable harm that is scientifically plausible but uncertain, actions shall be taken to avoid or diminish that harm"'.*

'The Council of Europe Resolution 1815 (46): "Take all reasonable measures to reduce exposure to electromagnetic fields, especially to radio frequencies from mobile phones, and particularly the exposure to children and young people who seem to be most at risk from head tumours…Assembly strongly recommends that the ALARA (as low as reasonably achievable) principle is applied, covering both the so-called thermal effects and the athermic [non-thermal] or biological effects of electromagnetic emissions or radiation" and to "improve risk-assessment standards and quality"'.

'The Nuremberg code (47) applies to all experiments on humans, thus including the roll-out of 5G with new, higher

RF-EMF exposure. All such experiments: "should be based on previous knowledge (e.g., an expectation derived from animal experiments) that justifies the experiment. No experiment should be conducted, where there is an a priori reason to believe that death or disabling injury will occur; except, perhaps, in those experiments where the experimental physicians also serve as subjects," Nuremberg code pts 3-5 (47). Already published scientific studies show that there is "a priori reason to believe" in real health hazards'.

'The European Environment Agency (48) is warning for "Radiation risk from everyday devices" in spite of the radiation being below the WHO/ICNIRP standards (49). EEA also concludes: "There are many examples of the failure to use the precautionary principle in the past, which have resulted in serious and often irreversible damage to health and environments…harmful exposures can be widespread before there is both 'convincing' evidence of harm from long-term exposures, and biological understanding [mechanism] (50) of how that harm is caused"'.

'Safety guidelines' protect the industry, not health. *'The current ICNIRP "safety guidelines" are obsolete. All proofs of harm mentioned above arise although the radiation is below the ICNIRP "safety guidelines" (49). Therefore new safety standards are necessary. The reason for the misleading guidelines is that "conflict of interest of ICNIRP members (10) due to their relationships with telecommunications or electric companies undermine the impartiality that should govern the regulation of Public Exposure Standards for non-ionizing radiation…To evaluate cancer risks it is necessary to include scientists with competence in medicine, especially oncology'.*

'The current ICNIRP/WHO guidelines for EMF are based on the obsolete hypothesis that "The critical effect of RF-EMF exposure relevant to human health and safety is heating of exposed tissue" (51). However, scientists have proven that many different kinds of illnesses and harms are caused without heating ("non-thermal effect") (52) at radiation levels well below ICNIRP guidelines'.

The authors thus urge the EU to carry out the following. *i) 'To take all reasonable measures to halt the 5G RF-EMF expansion until independent scientists can assure that 5G and the total radiation levels caused by RF-EMF (5G together with 2G, 3G, 4G, and WiFi) will not be harmful for EU-citizens, especially infants, children and pregnant women, as well as the environment'. ii) 'To recommend that all EU countries, especially their radiation safety agencies, follow Resolution 1815 and inform citizens, including, teachers and physicians, about health risks from RF-EMF radiation, how and why to avoid microwave radiation, particularly in/near e.g., daycare centers, schools, homes, workplaces, hospitals and elderly care'. iii) 'To appoint immediately, without industry influence, an EU task force of independent, truly impartial EMF-and-health scientists with no conflicts of interest (to re-evaluate the health risks and: a) To decide about new, safe "maximum total exposure standards" for all microwave radiation within EU. b) To study the total and cumulative exposure affecting EU-citizens. c) To create rules that will be prescribed/enforced within the EU about how to avoid exposure exceeding new EU "maximum total exposure standards" concerning all kinds of EMFs in order to protect citizens, especially infants, children and pregnant women'. iv) 'To prevent the wireless/telecom industry through its lobbying organizations from persuading EU-officials to make decisions about further propagation of RF radiation including 5G in Europe'. v) 'To favor and implement wired digital telecommunication instead of wireless'.*

First reply from the EU. A reply from the EU was sent on October 13, 2017 by the Directorate-General Health and Food Safety (Public health, country knowledge, crisis management) in Luxembourg. It was not replied to by the Commissioner Andriukaitis, but instead by Mr. John F. Ryan, Director (for the full text please see: http://www.5gappeal.eu/wp-content/uploads/2018/06/reply_ryan.pdf). Some paragraphs are presented below:

'It is worth underlining that for the Commission health protection is always taken into account in all of its proposals. There is consistent evidence presented by national and international bodies (International Commission on Non Ionising Radiation Protection - ICNIRP, Scientific Committee on Emerging and Newly Identified Health Risks - SCENIHR) that exposure to electromagnetic fields does not represent a health risk, if it remains below the limits set by Council Recommendation 1999/519/EC (https://ec.europa.eu/health//sites/health/files/electromagnetic_fields/docs/emf_rec519_en.pdf)'.

'The Scientific Committee on Emerging and Newly Identified Health Risks, which is independent of the Commission, has a standing mandate to provide this update'.

'It has already produced five opinions. The last opinion was adopted in January 2015 on "Potential health effects of exposure to electromagnetic fields". (https://ec.europa.eu/health/scientific_committees/emerging/docs/scenihr_o_041.pdf)'.

'These scientific opinions have not provided any scientific justification for revising the exposure limits (basic restrictions and reference levels) under Council Recommendation 1999/519/EC'.

'Digital technologies and mobile communication technologies, including high speed internet, will be the backbone of Europe's future economy, allowing all citizens to be connected. At the same time, all citizens deserve appropriate protection against electromagnetic fields from all types of sources including from wireless devices'.

'Most 5G networks are expected to use smaller cells than previous generations with lower electromagnetic fields exposure levels. This is confirmed by the experience so far gained. The introduction of 3G and 4G has not increased exposure from environmental fields and this has been published also in peer-reviewed journals. In particular, the introduction of 3G has lowered exposure of mobile phone users for calls, compared to 2G'.

'Related to the issue of the alleged conflicts of interests, the Commission is not aware of any conflicts of interests of members of international bodies such as ICNIRP or the members of SCENIHR. Please be informed that the Ombudsman conclusion in case 208/2015/P concerning conflicts of interests in a Commission expert group on electromagnetic fields is that there was no maladministration by the European Commission (https://www.ombudsman.europa.eu/en/cases/decision.faces/en/78175/html.bookmark)'.

'Please be assured that the Commission will pursue scrutiny of the independent scientific evidence available to ensure the highest health protection of our citizens'.

Comment: There are obvious misconceptions in this reply such as: *'The introduction of 3G and 4G has not increased exposure from environmental fields and this has been published also in peer-reviewed journals'.* On the contrary, numerous peer-reviewed articles have demonstrated that exposure to ambient RF radiation has increased substantially, as discussed (3-6).

In addition, the statement that: *'the Commission is not aware of any conflicts of interests of members of international bodies such as ICNIRP or the members of SCENIHR'* does not represent the scientific evidence of inherent conflicts of interest both in ICNIRP and SCENIHR (9,10). The very Commission seems to be ill-informed or even misinformed, as the EU seems to take information mainly from these two fraudulent organizations, but not from independent researchers. The EU does not seem to rely on sound science and thereby downplays the RF-related risks (7-12,53,54).

b) First rebuttal to the EU and the response. On November 13, 2017, a rebuttal was sent to the EU Commissioner of Health, Dr Andriukaitis. The whole letter can be found at: https://www.environmentandcancer.com/letter-to-vytenis-andriukaitis-13-11-2017/.

*'We suppose that you know that Director John F. Ryan, October 13, 2017 replied (Ares 2017 5015409 - Reply to the EU 5G-appeal, and that he said: "There is **consistent evidence** that exposure to electromagnetic fields **does not represent a health risk… if below the limits** …" His conclusion is based on the opinions of ICNIRP and SCENIHR'.*

'As early as February 1, 2016, in a Comment on SCENIHR to Mr. Ryan it was shown in article and letter by Drs. *[Sage], Carpenter and Hardell, representing BioInitiative and ECERI, that: "The evidence in the SCENIHR Final Opinion on EMF **clearly and convincingly establishes the potential for health effects of exposure to electromagnetic fields** [EMF]. Based on the evidence provided in this Opinion, the Committee is obligated to draw to the attention of the [EU] Commission that EMF is a new and emerging problem that may pose an actual or potential threat"' (55).*

'In spite of all this, Mr Ryan in his reply to us still continues to claim that EMF 'does not represent a health risk' and - without any other references than ICNIRP and SCENIHR - defends industry's standpoint that EMFs are harmless if below the ICNIRP "safety guidelines". In addition he ignores the IARC evaluations on both ELF-EMF and RF-EMF to be 'possible' human carcinogens, Group 2B'.

*'In the 5G-Appeal we urge EU to appoint a truly independent expert group of EMF-and-health researchers (contrary to ICNIRP and SCENIHR) to decide about new safe guidelines for EMF exposure. It is imperative to **immediately apply EU:s Precautionary Principle (and ALARA)** enabling rapid response to stop distribution of 5G products in order to diminish the harm that has already been proven by scientists. A **European pan-epidemic** may follow if you don't do so'.*

Second reply from EU on 29 November, 2017. This was sent from the European Commission, Cabinet of Commissioner Vytenis Andriukaitis, Head of Cabinet Brussels, written by Arūnas Vinciunas. The full reply can be found at: http://www.5gappeal.eu/wp-content/uploads/2018/06/reply_vinciunas.pdf).

'When Mr Ryan answered your email, in which you stated your disagreement with the Commission's stance on the 5G appeal, he presented the conclusions of roughly two decades of research on the potential health effects of EMF, and the views expressed in the Scientific Opinions produced by the independent Scientific Committees. [ICNIRP - International Commission on Non-Ionizing Radiation Protection and SCENIHR - Scientific Committee on Emerging and Newly Identified Health Risks]. The Committee's last Opinion on EMF, published in 2015, is based on hundreds of peer-reviewed studies published worldwide and is the fourth Opinion on EMF published since EMF legislation was adopted in 1999. The Committee's conclusion in this latest Opinion was based on exposure studies, epidemiological studies and in vivo and in vitro studies, and studies on any suggestions of causality were considered for the weighting'.

'The Commission services are confident that the advice provided by the Scientific Committees is unbiased, accurate and scientifically sound and therefore do not feel it necessary to appoint an independent expert group of EMF-and-health researchers to discuss new safe guidelines for EMF exposure'.

'The recourse to the EU's Precautionary Principle to stop the distribution of 5G products appears too drastic a measure. We first need to see how this new technology will be applied and how the scientific evidence will evolve. Please rest assured that the Commission will keep abreast of future developments in view of safeguarding the health of the European citizens at the highest level possible and in line with its mandate'.

Comment: This reply from EU is far from adequate. It does not represent a sound evaluation of the RF-related radiation risks based on published peer-reviewed studies. This is again outlined in our response to the EU.

c) Second rebuttal to the EU and the response. On January 17, 2018, a letter was sent to Dr. Vytenis Andriukaitis, EU Commissioner of Health. Sections of this letter are presented below and the full text can be found at: https://www.environmentandcancer.com/letter-to-vytenis-andriukaitis-and-donald-tusk-17-01-18/.

'Following the letter and the Scientist Appeal calling for a moratorium on 5G ("The 5G Appeal"), which we sent to your office, we received a response from Director John F. Ryan on October 13, 2017 and then, upon our reply, a letter from Mr. Arūnas Vinciūnas dated 29.11.2017'.

'Despite the conclusive evidence presented in our letters, both Director Ryan and Mr. Vinciūnas gave generic responses and continued to claim that EMF "does not represent a health risk". In doing so they only refer to ICNIRP and SCENIHR opinions without explaining why they disregarded the compelling evidence and references under the 5G-Appeal headline: "Harmful effects of RF-EMF exposure are already proven"'.

'The ICNIRP exposure limits are dependent on an unproven hypothesis that "only heat from EMF can cause health hazards". This hypothesis has clearly been rejected in a large number of scientific studies'.

'Both EU officials defend the industry-supportive standpoint that EMFs are harmless if below the ICNIRP "guidelines". However, many of the scientists on both ICNIRP's and SCENIHR's committees are connected to the telecom industry with obvious conflicts of interest'.

'Mr Vinciūnas stated in his letter: "The recourse to the EU's Precautionary Principle to stop the distribution of 5G products appears ***too drastic a measure****." Mr Vinciūnas finishes his letter: "we need to see … how the scientific* ***evidence will evolve****"'.*

'According to Communication from the Commission on the precautionary principle: "Whether or not to invoke the Precautionary Principle is a decision exercised where scientific information is insufficient, inconclusive, or uncertain and where there are indications that the possible effects on the environment, or human, animal or plant health may be potentially dangerous and inconsistent with the chosen level of protection." That describes the situation with 5G perfectly. Existing data shows that 5G frequencies [radiations] are hazardous. However, additional studies will be necessary to fully determine the extent of the risk'.

Third reply from the EU. This letter was replied to on April 27, 2018 by Mr. Arūnas Vinčiūnas from the Cabinet of Commissioner Vytenis Andriukaitis. For the full third reply to our appeals please see: https://www.environmentandcancer.com/answer-from-arunas-vinciunas-27-04-2018/.

'Thank you very much for your letter of 15 March 2018 which was also transmitted by email on 19 March. Commissioner Andriukaitis has asked me to reply to you on his behalf'.

'Finally, let me refer to the previous correspondence you have had with John F. Ryan, Director of Public Health and me (29 November 2017, 13 October 2017 and 19 February 2018) where we have comprehensively explained our position with regard to the arguments you have raised. It is my view that we have now extensively deliberated on the matter and that we should refrain from further repetition'.

'Please rest assured that the Commission will remain committed to safeguarding the health of the European citizens, at the highest level possible and in line with his mandate'.

d) Third rebuttal to the EU and the response. This rebuttal had the title *"Request for a moratorium on the 5G rollout. Request for guidelines based on independent research. Request for documents showing that 5G is safe".* On May 20, 2019 a letter with these requests was sent to Dr Karmenu Vella, EU Commissioner of Environment and Dr Vytenis Andriukaitis, EU Commissioner of Health. For the full text please see: https://www.environmentandcancer.com/letter-to-vytenis-andriukaitis-20-05-2019/.

'We make reference to the Precautionary Principle (PP) (56) It "enables a rapid response to be given in the face of a possible danger to human health…institutions may take protective measures without having to wait until the reality… of risks become apparent … preventive action should be taken" (57). Research confirms 5G to be a risk to all life on earth'.

'With this communication we touch upon three points:' i) 'Firstly, we request in the 5G Appeal to EU (www.5gappeal.eu), of which you are a public servant and representative, to declare an immediate ***moratorium*** *on 5G deployment. The 5G appeal to EU is now confirmed by 230+ truly independent scientists and physicians from 36 countries. The Space 5G appeal (58) has more than 83,000 affirmations from 168 countries. According to PP (56) and EU IP/00/96 (59) "protection of health takes precedence over economic considerations."' ii) 'Secondly, we ask for groups of truly industry-independent researchers to establish* ***new guidelines for exposure****. An "In-depth analysis" of the deployment of 5G (60), published by EU in April 2019, needs to be seriously considered. It stated that" One aspect, for example, that is not well understood today is the unpredictable propagation patterns that could result in unacceptable levels of human exposure to electromagnetic radiation."(p. 6)'. iii) 'Thirdly, with this letter we are formally requesting, in accordance with Art. 42 (61) on EU Fundamental Rights,* ***access to all documents*** *in your possession, either created by you or at your disposal, related to the effects of EMF to human health and the environment. Once in possession of such a list, we will decide which of those documents, if any, are of interest and show that 5G is safe. The list of the documents, and the ways to access them, should be sent to the email addresses below'.*

'We note that, while the EU is eagerly promoting the rollout of 5G, a new EU report admits (60) "the problem is that currently it is not possible to accurately simulate or measure 5G emissions in the real world" (p. 12). "Significant concern is emerging over the possible impact on health and safety arising from potentially much higher exposure to radiofrequency electromagnetic radiation arising from 5G" (p. 4). The EU report also stresses dangers: "Increased exposure

may result not only from the use of much higher frequencies in 5G but also from the potential for the aggregation of different signals, their dynamic nature, and the complex interference effects that may result, especially in dense urban areas." (p. 11)'.

Fourth reply from the EU. Finally, a response was delivered by the EU on September 5, 2019, although with reference to the wrong date of our letter. It was sent by Arunas Vinciunas from the Cabinet of Commissioner Vytenis Andriukaitis. The full response can be read at: https://www.environmentandcancer.com/answer-from-arunas-vinciunas-05-09-2019/.

'Thank you for your email of 7 July 2019 to Commissioner Andriukaitis in which you request to halt the 5G expansion in the EU immediately in order to allow a moratorium for industry independent research. Commissioner Andriukaitis has asked me to reply to you on his behalf'.

'In my latter note to you I already expressed my view that we had extensively deliberated on the matter and that we should refrain from further repetition'.

'As regards your request to halt the launch of the new 5G technology, I would like to confirm the view already expressed in my note of 29 November 2017 to you that stopping the distribution of 5G products appears too drastic a measure. I repeat that first there is a need to see how this new technology will be applied and how the scientific evidence will evolve'.

'Concerning your call for a scientific evaluation and new guidelines for exposure, the second point you have raised, let me stress that the Commission will review the situation once the review of the guidelines issued by the International Commission on Non-Ionizing Protection (ICNIRP) will be finalised which is expected in due course'.

'As regards your third point, documents related to the effects of electromagnetic fields to human health and the environment, please be referred to the opinion of the Commission's Scientific Committee on Emerging and Newly Identified Health Risks of 20 January 2015 on potential health effects of exposure to electromagnetic fields (EMF) (https://ec.europa.eu/health/scientific_committees/emerging/docs/scenihr_o_041.pdf) that provides an extensive list of references to scientific literature on this issue'.

Comment on the fourth reply from the EU appeal: There is no new evidence of the safety in this letter from EU compared with the earlier replies. Of note, the EU relies on documentation of risk only on old and biased selection of references in one single report from SCENIHR (https://ec.europa.eu/health/scientific_committees/emerging/docs/scenihr_o_041.pdf). Thus, EU officials still seem to base the evaluation of the health risks on reports from the ICNIRP and SCENIHR that have been seriously criticized. Of note, the EU relies on a report from 2015 as to scientific publications on the safety of 5G, a technology that was not developed during that time. This suggests that perhaps the EU is reluctant to deal with the safety issues associated with 5G technology.

e) Fourth rebuttal to the EU. On October 24, 2019 a fourth rebuttal was sent to the EU (https://www.environmentandcancer.com/letter-to-arunas-vinciunas-24-10-2019). We wrote that *'Specifically now, as we wish to assist the Commissioner in giving due response, it can be further specified from this side that we need the **list of documents** related to EMFs created by RF/Radiofrequencies (so: not by ELF) and even more specifically, to the list of those documents based on which the Commission is basing its current position that 5G should not be stopped nor subject to a moratorium (see the statement of your letter that "first there is a need to see how this new technology will be applied and how the scien6fic evidence will evolve"). We leave aside our total disagreement on the merits of such position at this time: formally, we are entitled to receive from you such a list of documents based on which the Commissioner determined that 5G is safe. Based on that list we will decide which of those documents, are of interest. Please provide such list by email no later than October 31, 2019. This is urgent'.*

Fifth reply from the EU. In this response, dated December 19, 2019, it was stated that new ICNIRP guidelines are expected. Thus, the same approach to this issue as previously and no new commitment (https://www.environmentandcancer.com/answer-from-martin-seychell-19-12-2019).

Appeals to the Nordic Prime Ministers

The 5G Appeal was also sent to the Nordic Prime Ministers (https://www.environmentandcancer.com/letter-to-nordic-ministers-27-6-2018/); (https://www.environmentandcancer.com/letter-to-nordic-ministers-5-3-2019/). The only reply, dated March 29, 2019, was sent from the Swedish government (Ministry of Enterprise and Innovation, Mari Mild). It was stated that the government relies on Swedish Radiation Safety Authority (SSM) and their yearly update of health risks and that no new health risks have been reported. According to the letter there is no reason for a moratorium on the deployment of 5G, see (in Swedish) (https://www.miljoochcancer.com/svar-fran-naringsdepartementet-29-3-2019/). SSM relies on ICNIRP.

Discussion

Our experience with the EU and the Governments of the Nordic countries suggests that the majority of decision makers are scientifically uninformed on health risks from RF radiation (62). In addition, they seem to be uninterested to being informed by scientists representing the majority of the scientific community, i.e., those scientists who are concerned about the increasing evidence or even proof of harmful health effects below the ICNIRP guidelines (www.emfscientist.org). Instead, they rely on evaluations with inborn errors of conflicts, such as ICNIRP. In fact, the ICNIRP, with the support of WHO and major telecommunications companies, has been rather successful in implementing their views in the EU and worldwide. Their guidelines seem to be based on the omission of scientific facts. Thus, their possible ignorance of the health risks is of concern, as well as their reluctance to adhere to warnings from large numbers of scientists around the world.

It is striking that 5G is deployed without previous scientific evaluation of health risks. Not only cancer risks, but also other health effects such as fertility, cognitive and neurobehavioral effects, oxidative stress and electromagnetic hypersensitivity (EHS) have been associated with RF exposure [for a more detailed discussion on this tope, please see previous publications (1,7,8,28,35)]. It is thus noteworthy that the ICNIRP thermal paradigm is still used for the evaluation of the health risks associated with RF radiation. One issue of major concern is that there seems to be conflicts of interest among persons in the evaluating groups. Furthermore the same persons may often be found in different bodies, thereby in fact citing themselves representing a cartel (https://www.saferemr.com/2018/07/icnirps-exposure-guidelines-for-radio.html). This has been outlined in peer-reviewed publications (9,10).

This is also an ethical question. Thus, it would not be possible to test a new drug on individuals without information and signed permission by each individual. Certainly, this principle should apply to 5G that is furthermore, mandatory. Exposure to RF radiation from 5G must be regarded as a medical experiment with potential health risks, some known and expected based on current knowledge, some unknown since this is a new untested technology. A letter of information to those exposed must be sent for informed consent. However, it must be concluded that such a letter, affirming no risk, cannot be formulated based on the limited number of studies on 5G, in fact most of them with no assurance of no risks.

This is also a moral question for all the individuals involved in the propagation of 5G. It is to be noted that individuals within e.g., ICNIRP, national governmental bodies and the EU, partly a cartel, seem to neglect scientific warnings. They instead seem to follow the no-risk paradigm. It is thus questionable as to how it is possible to thereby disregard the diseases caused by this technology and to not consider the affected persons.

Taking the history of e.g., tobacco and smoking and the long period of time it took for cancer classification into account, it is fully understandable that RF radiation is still in the beginning of that history. However, if no action is currently taken, the costs to society will most likely be very high in terms of premature deaths, deteriorated public health and damage to the ecological system. It is however, important to publish the history of neglected RF radiation warnings. The EU seems to perhaps lacking in that respect. It must be concluded that the polluter has to pay the full cost of harm from this technology (63). Those in responsible positions in governments and organizations intended to protect the public and the environment from harm (WHO and ICNIRP), but who fail to do so by ignoring the increasing warnings from scientists worldwide about the dangers of 5G, should also be held responsible for the harm to the public that they thereby induce (64). No doubt damage to the environment by the business sector may be substantial (https://www.theguardian.com/environment/2010/feb/18/worlds-top-firms-environmental-damage).

The EU principle that the Polluter Pays (Article 191, pt 2) states: *'Union policy on the environment shall aim at* ***a high level of protection taking*** *into account the diversity of situations in the various regions of the Union.* ***It shall be based on the precautionary principle*** *and on the principles that* ***preventive action should be taken****, that environmental damage should as a priority be rectified at source and that* ***the polluter should pay****'*. (https://eur-lex.europa.eu/LexUriServ/LexUriServ.do?uri=CELEX:12008E191:EN:HTML).

'The fundamental principle of this Directive should therefore be that an operator whose activity has caused the environmental damage or the imminent threat of such damage is to be held financially liable, in order to induce operators to adopt measures and develop practices to minimise the risks of environmental damage so that their exposure to financial liabilities is reduced' (65) (https://eur-lex.europa.eu/legal-content/EN/TXT/HTML/?uri=CELEX:32004L0035&from=EN).

The industry tries to convince us that the super high frequencies of 5G are so weak and its millimeter waves will penetrate only the outer surface of the skin. The opposite was proven in USSR research already in 1977 (https://www.cia.gov/library/readingroom/docs/CIA-RDP88B01125R000300120005-6.pdf). High frequencies (37-60 GHz), which will be used in 5G, caused several kinds of detrimental effects in experimental rats. The high frequencies seem to be worse than the lower frequencies. The USSR experiments were made more than 40 years ago - when we had no digital pulsed radiation - with a generator producing sinus curves. Peaks of pulsed radiation used in 5G with unpredictable intensity changes seem to be an important parameter for the bioactivity of RF radiation (29).

In conclusion, this article demonstrates that the EU has given mandate to a 13-member, non-governmental private group, the ICNIRP, to decide upon the RF radiation guidelines. The ICNIRP, as well as SCENIHR, are well shown not to use the sound evaluation of science on the detrimental effects of RF radiation, which is documented in the research which is discussed above (9,10,21-24,54,55). These two small organizations are producing reports which seem to deny the existence of scientific published reports on the related risks. It should perhaps be questioned whether it is in the realm of protecting human health and the environment by EU and whether the safety of EU citizens and the environment can be protected by not fully understanding the health-related risks.

Review article

Health effects of electromagnetic fields on children

Jin-Hwa Moon, MD, PhD
Department of Pediatrics, Hanyang University School of Medicine, Seoul, Korea

In today's world, most children are exposed to various manmade electromagnetic fields (EMFs). EMFs are electromagnetic waves less than 300 GHz. A developing child's brain is vulnerable to electromagnetic radiation; thus, their caregivers' concerns about the health effects of EMFs are increasing. EMF exposure is divided into 2 categories: extremely low frequencies (ELFs; 3–3,000 Hz), involving high-voltage transmission lines and in-house wiring; and radiofrequencies (RFs; 30 kHz to 300 GHz), involving mobile phones, smart devices, base stations, WiFi, and 5G technologies. The biological effects of EMFs on humans include stimulation, thermal, and nonthermal, the latter of which is the least known. Among the various health issues related to EMFs, the most important issue is human carcinogenicity. According to the International Agency for Research on Cancer's (IARC's) evaluation of carcinogenic risks to humans, ELFs and RFs were evaluated as possible human carcinogens (Group 2B). However, the World Health Organization's (WHO's) view of EMFs remains undetermined. This article reviews the current knowledge of EMF exposure on humans, specifically children. EMF exposure sources, biological effects, current WHO and IARC opinions on carcinogenicity, and effects of EMF exposures on children will be discussed. As well-controlled EMF experiments in children are nearly impossible, scientific knowledge should be interpreted objectively. Precautionary approaches are recommended for children until the potential health effects of EMF are confirmed.

Key words: Electromagnetic field, Extremely low frequency, Radiofrequency, Smart device, Child

Key message

- The nervous systems of children are more vulnerable to the effects of electromagnetic waves than adults.
- The exposure to electromagnetic fields (EMFs) among children should be minimized.
- According to International Agency for Research on Cancer EMFs are possibly carcinogenic, it should not be overlooked or interpreted with bias.

Introduction

Electromagnetic radiation is generated from natural environments such as the solar energy and geomagnetic field or from manmade sources. With scientific and technological advancements, our everyday environments are filled with various manmade electromagnetic fields (EMFs). EMFs are invisible and generated from electrical lines, transmission towers, telecommunications, home appliances, mobile phones, WiFi, and base stations. An increasing number of children use computers and iPads for school, entertainment, and social activities. Even infants can be exposed to EMFs in the residential environment or by the direct use of electronic devices (Fig. 1).

There are 2 main categories of EMFs: extremely low frequency (ELF) and radiofrequency (RF) waves.[1-3] ELFs can be generated from electrical lines or transmission towers, issues of which have been investigated for the last several decades. RFs can be generated from mobile phones and smart devices and the recent 5th-generation (5G) technologies. The human effects of RFs are less evident and more difficult to study than those of ELFs.

In Korea, general measures have been recommended to reduce EMF exposure such as reducing the use of electronic devices or using them away from the body. However, little is known about the exact amount of daily EMF exposure that can affect a child's health and whether the effects of EMF exposure are similar to those of adults. The developing nervous system is more conductive and absorbs more electromagnetic energies than those of adults.[4] Therefore, different standards are required to protect children.

In recent years, pediatricians have become increasingly asked about children's use of electromagnetic devices and the risks of EMF exposure. Thus, more knowledge about pediatric exposure to electromagnetic radiation is required than any other time before. Thus, this article reviews the current knowledge about the health effects of EMF exposure on children. The World Health Organization's (WHO's) opinions and other scientific researches will be critically reviewed, and the precautionary principle to reduce the negative effects of EMF on children will be emphasized.

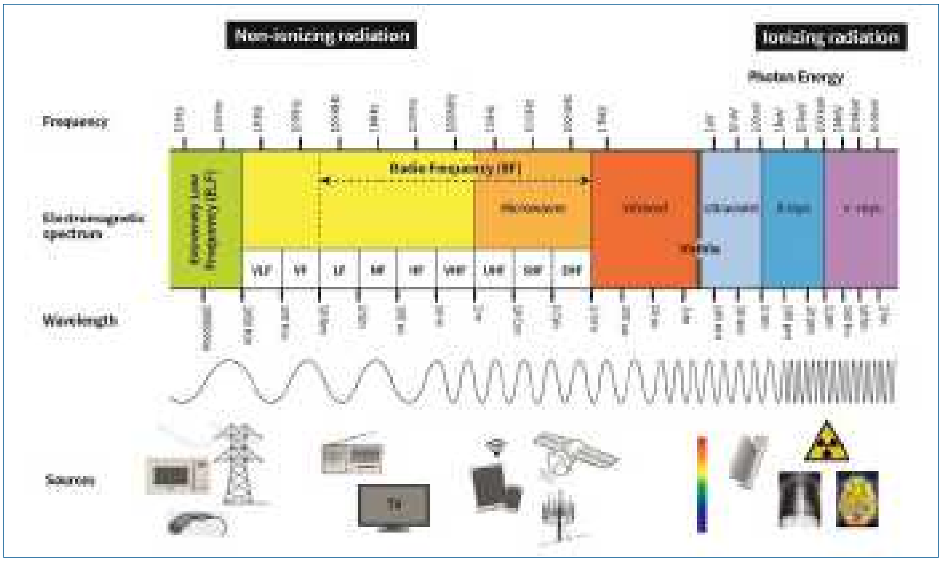

Fig. 1. The electromagnetic spectrum. Frequencies (expressed by hertz, Hz) increase from left to right, while wavelengths decrease from right to left. Ionizing radiations are x-rays and γ-rays. EHF, extremely high frequency; HF, high frequency; LF, low frequency; MF, medium frequency; SHF, super-high frequency; VF, voice frequency; VHF, very high frequency; VLF, very low frequency; UHF, ultra-high frequency.

Sources of EMF exposure

Whenever electrical current flows, both electrical and magnetic fields are generated, known as EMFs. Electric field strength is measured as volts per meter (V/m), while magnetic field strength is measured as amperes per meter (A/m). A magnetic field can be measured as magnetic flux density (Tesla).

The electromagnetic spectrum is categorized into a frequency range: ELF, RF, infrared, visible, ultraviolet, and ionizing radiations (x- and γ-radiation).[1,3] EMF refers to waves less than 300 GHz, which includes most of the frequencies in everyday exposure. The lowest frequencies (3–3,000 Hz) are referred to as ELF-EMF, while the higher frequencies (30 kHz to 300 GHz, under infrared) are referred to as RF-EMF (Fig. 2).

1. Extremely low-frequency EMFs

ELF-EMFs are generated from electricity, electrical machines, transmission towers, and high-voltage lines. In Korea, electric power is operated at 60 Hz. More EMFs are absorbed with the use of appliances that are close to the body (e.g., hair dryers, bidets, massagers, and electric blankets). The general recommendation is that electrical appliances should be used at least 30 cm away from the body (http://www.emf.or.kr/general/html/life/guideline.pdf).

2. Radiofrequency EMFs

RF-EMFs are generated from mobile phones, smart devices, WiFi, base stations, and radars. Radio or television transmitters and base stations can be large sources of RF exposure. Mobile phones generate more electromagnetic waves when used in a fast-moving subway or train or when searching for a base station before the ring back tone.[5]

Biological effects of EMFs

The main effects of EMFs on the human body are stimulation, thermal, and nonthermal. Stimulation effects involve the nerves and muscles at a high EMF, can be used for medical devices, and can cause electrical shock at very high stimulation levels. Thermal effects involve an increase in body temperature. Hot senses of the ear or body during mobile phone or laptop use are some examples. Nonthermal effects result from recurrent long-term exposure and may be related to the so-called electromagnetic hypersensitivity syndrome or neurodevelopmental disorders. However, the nonthermal effect is the least well investigated.[6]

The effects of EMF exposure differ with respect to frequencies and strength. For frequencies less than 300 GHz, limitation levels for human protection have been well established for public and occupational workers.[7,8] From 100 kHz to 10 GHz, which includes the use of mobile phones, limitation level is expressed as a specific absorption rate (SAR, W/kg).[2,8]

One of the major issues of EMF involves human carcinogenesis. Since the first report on residential ELF-EMF and childhood leukemia in 1979, several studies have investigated this association.[1,2,7] However, because of the nature of electromagnetic radiation, most studies were based on epidemiological data or animal experiments.

Animal studies on prenatal RF exposure demonstrated the deleterious effects of RF-EMF on the brain. Prenatal exposure to 900 MHz resulted in substantial loss of granule cells[9] or a significant reduction in pyramidal neurons.[10] Mice exposed to in utero RF from cellular telephones were hyperactive and demonstrated memory impairment after birth.[11] EMFs from mobile phones changed the blood-brain barrier's permeability and damaged neurons in the brains of exposed rats.[12-14]

Brain oxidative stress and epigenetics are considered biological

Fig. 2. Various sources of electromagnetic fields (EMFs). Extremely low-frequency EMFs are generated by electricity, various home appliances, in-house wiring, and outside high-voltage lines. Radio frequency EMFs waves are generated by mobile phones, smart devices, WiFi, base stations, and other devices.

mechanisms of RF-EMF effects. Several theories suggest that EMF exposure results in oxidative stress and reactive oxygen species and loss of cells and blocks their production.[15] Oxidative stress parameters increase lipid hydroperoxide and myeloperoxidase activity in immature rats.[16] RF-EMF exposure may change deoxyribonucleic acid methylation, histone modification, chromatin remodeling, and microribonucleic acid.[16-18] However, the results of studies on brain oxidative stress induced by EMF are inconsistent.

In Korea, many websites for public and nonpublic institutions provide information aiming to improve public awareness and EMF knowledge.[19-22] This information includes large amounts of data on human limitation levels, EMF measurements of electronic products, base station information, general safety guidelines, and false beliefs. Although the websites provide general information for public awareness, they sometimes conclude that the public concerns regarding carcinogenicity and nonthermal effects are exaggerated and have insufficient evidence. However, such conclusions may be hasty. Because evidence of the relevant websites is often based on WHO fact sheets, it is necessary for clinicians to review the WHO opinion and evaluate other scientific evidence objectively.

On the other hand, some individual websites or personal blogs deliver scientifically unreasonable negative information to users. Such messages exaggerate claims and interfere with reasonable discussions about EMF health effects.

Different tones for human carcinogenicity

1. Carcinogenicity of ELF-EMF

In 1996, the WHO organized an international EMF project task group to investigate the potential health risks of EMF-associated technologies. In the resulting fact sheet in 2007, the WHO concluded that there were no substantive health issues related to ELF electric fields at levels generally encountered by the public.[7] This position was based on findings and reviews of the WHO task group as well as the International Agency for Research on Cancer (IARC, 2002) and International Commission on Non-Ionizing Radiation Protection (2003).[2,7,23] The WHO task group referenced the IARC monograph evaluating the carcinogenic risks in humans in 2002 that classified ELF as a possible carcinogen.[2] However, the task group commented that the epidemiological evidence of carcinogenicity was weakened by methodological problems such as potential selection bias.[7]

In fact, the IARC's 2002 monograph evaluated a number of scientific studies on ELF electronic and magnetic fields and childhood and adult cancers.[2] In the part about the effects on children, it stated that "pooled analyses showed 2-fold excess risk for exposure to ELF magnetic fields above 0.4 μT and a relative risk of 1.7 for exposure above 0.3 μT.".[2] The IARC concluded that ELF magnetic fields were possibly carcinogenic to humans (Group 2B) and that the association between child leukemia and a high magnetic field was unlikely to be due to chance.[2] In contrast to ELF magnetic fields, evidence on the association between ELF electric fields and leukemia was inadequate, and the associations between other childhood brain tumors or cancers and ELF were inconsistent.[2]

The IARC is a working group under the auspices of WHO. Despite this, the different views between the WHO and the IARC may have originated from the differences in their respective members. Many committee members of the WHO's EMF project were involved with electricity-associated industries, whereas the IARC membership included more epidemiologists and health specialists.[24] In Korea, several public websites on EMF safety frequently cite the WHO EMF opinion. Some citations seem to have been changed through self-citation, which may cause the misleading interpretation that there is no scientific evidence of carcinogenicity.

2. Carcinogenicity of RF-EMF

A large international case-control study (INTERPHONE study, 2000) that aimed to determine the association between adult brain tumor risk and mobile telephone use reported no overall increase in brain tumor risk with the use of mobile phones.[25] However, in the 10th highest decile of cumulative call time (≥1,640 hours), the odd ratios were 1.4 for glioma and 1.15 for meningioma.[25] Glioma tended to occur more commonly in the temporal lobe on the side of usual phone use.[25] After the INTERPHONE study, in 2013, the IARC published another monograph evaluating the carcinogenic risks of RF-EMF on humans.[3] Similar to ELF magnetic fields, the IARC classified RF-EMFs as "possibly carcinogenic to humans (Group 2B)."[3]

In 2014, the WHO also published the following fact sheet on mobile phone EMF and public health.[26] Similar to ELF, the WHO opinion was undetermined. It referenced the IARC's classification of mobile phone use as possibly carcinogenic to humans. However, the WHO group repeated the comment that the "biases and errors limit the strength of these conclusions and prevent a causal interpretation."[26] Such undetermined views of the WHO on the adverse effects of RF or ELF-EMF have been criticized by several scientist groups, which have requested that the WHO should reevaluate all health effects of EMF and include experts from all related fields such as health, medicine, and engineering to reassess the effects of EMFs.[24,27,28]

Other EMF effects on children's health

In everyday life, children are exposed to indoor and outdoor EMFs. Although well-designed case-control studies are lacking, we can consider the available data in hypothesizing about the effects of EMF on children.

1. ELF effects on and children

ELF from high-voltage power lines can affect children living near them; in fact, children can be continuously affected by low-level in-house wiring. Much of the results regarding ELF and children's health are based on epidemiologic studies with childhood leukemia as described in the previous section.

While conducting the international EMF project, the WHO conducted an international workshop on "Sensitivity of children to EMF exposure" (Istanbul, Turkey, June 2004) of both ELF and RF-EMF exposure. They concluded that there was no direct evidence that children were more vulnerable to EMF because very few studies assessed this topic.[29] However, considering the uncertain effects of EMF on children, the WHO recommended general measures such as reducing personal EMF exposure. They also recommended minimizing EMF exposure in schools, kindergartens, and any locations where children remain for a substantial part of the day.[1,29]

2. RF effects on children

Whether children are vulnerable to RF has been debated for the last 20 years, when children were widely exposed to mobile phones. Human and animal model studies yielded significant findings regarding cellular phone use: increased headache, sleep disruption, neurotransmitter release, synaptic plasticity alterations, and neuronal cell cycles.[30-34] However, the experimental environment and RF doses may differ from those of actual exposures.

The Korean study conducted in 1993–1999 involving 1,928 children with leukemia and 956 children with brain tumors. It revealed that the risk of leukemia was 2.15 times higher in the group living within 2 km from AM radio transmitters than in the group living more than 20 km from it.[35]

In 2000, the "Stewart report" by the UK Independent Expert Group on Mobile Phones declared that children may be more vulnerable to EMF than any other age groups.[4,36] They stated that "*children are exposed to electromagnetic waves over a longer life time than adults and their nervous systems are in the process of development. As the conductivity of the children is higher due to higher moisture and ionic content than adults, and more than adults, children's head absorbs a lot of RF energy*" (Fig 3).[4] Stewart's report suggested that children should not be encouraged to use mobile phones unnecessarily and that mobile phone companies should not promote their use in children.[4] Since Stewart's report, debate regarding the vulnerability of a child's brain surfaced from the Netherlands and Russia.[37,38]

3. Studies of mobile phone RF exposure in children

The skull thickness of adults is approximately 2 mm. However, the skull thickness of a 5-year-old child is approximately 0.5 mm and 1 mm in 10 years.[39] Therefore, radiation penetration is larger in children than in adults.[39,40] As a child's head diameter is smaller, the energy-absorbing "hot spots," the most sensitive parts of RF, are more pronounced.[41] Several engineering strategies to avoid the hazard of RF do not consider a child's head

Children may be more vulnerable to EMF than any other age groups.

- *Children are exposed to electromagnetic waves over a longer life time than adults.*
- *Their nervous systems are in the process of development.*
- *The conductivity of the children is higher due to higher moisture and ionic content than adults.*
- *Children's head absorbs a lot of RF energy more than adults.*

From "Stewart report" by the UK Independent Expert Group on Mobile Phones (2000) [4]

Fig. 3. The vulnerability of children to electromagnetic field exposure according to the UK Independent Expert Group on Mobile Phones. EMF, electromagnetic field; RF, radiofrequency.

https://doi.org/10.3345/cep.2019.01494

specificity.[6)]

The results of the study that assessed the associations between RF exposure and cell phone use, residential RF-EMF levels, and cognitive function tests were inconsistent.[42-46)] Ten-year-old children living in areas with higher RF exposure did not show any effects in most of the cognitive parameters; however, they did show lower verbal scores and higher internalizing and total problems.[46)] In a study of children aged 5–6 years, greater residential RF exposure from base stations and the presence of indoor sources were associated with improved inhibitory control and flexibility of cognition but also reduced visuomotor coordination.[47)]

The associations between RF exposure and mobile phone use and sleep in children are inconsistent.[48-50)] Habitual and frequent use of mobile phones was associated with lower sleep quality, while higher tablet use was associated with decreased sleep efficiency.[49)] Arousal and blue light may underlie these problems. Residential exposure to RF-EMF from base stations was not associated with sleep onset delay, night awakening, parasomnia, and daytime sleepiness in 7-year-old children; however, higher mobile phone use was associated with less favorable sleep duration, night awakening, and parasomnia.[50)]

Cell phone use by pregnant mothers during the pre- and postnatal periods can contribute to behavioral problems in children.[51)] In children exposed to cell phones during the pre- and postnatal periods, the odds ratio for behavioral problems was 1.8 after the adjustment of potential confounders.[52)]

Recently, the European Union-funded international study evaluating the association between RF exposure by mobile phones and brain tumor risk in children and adolescents (MOBI-KIDS) was conducted.[53)] This large study included nearly 900 eligible patients from 14 countries, including Korea, and the final results are still pending.[54)]

The 5G technologies using electromagnetic waves can make hyper-connected network environments capable of augmented reality and 3-dimensional service. The 5G frequency comprises 3.5-GHz and 28-GHz bands. The effect of the 3.5-GHz band on humans may be similar to that of 4G and can utilize the existing base station, but 28 GHz may be different to the human body and the base stations must be installed more closely. Therefore, the long term effects of 5G on children's health are unestablished. The impact of 5G technologies on children has never been evaluated.[55)]

4. Precautionary principles for children

International policies and advisory responses regarding children's exposure to RF-EMF vary. RF-EMF-related advisory policies for children are as follows: banning mobile phone advertising or sale to children, SAR labeling, and preferring wired connection to WiFi in schools. In Korea, only the policy of SAR labeling on mobile phone is strictly followed. Similar to other scientific uncertainties, precautionary principles should be followed for the EMF problem (EC, 2017).[56)] The meaning of precautionary principle is as follows: *when human activities may lead to morally unacceptable harm that is scientifically plausible but uncertain, actions shall be taken to avoid or diminish that harm (UNESCO 2015)*. For children, strict standards are required until scientific knowledge is established, specifically in facilities such as schools and preschools, where they stay longer. This article suggests precautions to reduce the risk of excessive EMF exposure in children (Table 1).

Table 1. Precautions to reduce the risk of excessive electromagnetic field (EMF) exposure in children

Children can be exposed to EMF by electronic devices, high-voltage transmission lines, mobile phones, WiFi, etc.
For parents: · Avoid long-term exposure to strong EMFs in home, school, or other places children spend much of their time. · Avoid using electrical devices within 30 cm of the body. · Avoid using smartphones directly against your child's head. · Keep your child's body from getting hot while using mobile phones. · Do not allow your child to use smart devices during meals or for the last hour before bed. · Note that the effects of various devices using virtual reality and WiFi have on the neural development of children remain unknown. · Most products that claim to reduce EMFs are ineffective or unproven. · Ask your child's pediatrician for information to guide your child's use of smart devices.
For teachers, policymakers, and commercial companies: · Teachers: Educate children on how to avoid excessive EMF exposure. · Policymakers: Create policies to reduce children's EMF exposure from the environment. · Commercial companies: Create products that reduce children's exposure to EMFs and issue warnings about them.

EMFs, electromagnetic fields.

Conclusion

The nervous systems of children are more vulnerable to the effects of electromagnetic waves than those of adults. Although studies on the effects of EMFs on children's health are unestablished, precautionary principles should be followed for children and the exposure to EMFs among children should be minimized. The fact that EMFs are possibly carcinogenic according to the IARC should not be overlooked or interpreted with bias, and the opinions of clinicians should be given more weight than those of industries in the establishment of safety policies for EMF use. Moreover, a study that assesses the effects of 5G frequency technology on children's health is required.

COMMENT

Health risks from radiofrequency radiation, including 5G, should be assessed by experts with no conflicts of interest

LENNART HARDELL and MICHAEL CARLBERG

The Environment and Cancer Research Foundation, SE-702 17 Örebro, Sweden

Received April 8, 2020; Accepted June 19, 2020

DOI: 10.3892/ol.2020.11876

Abstract. The fifth generation, 5G, of radiofrequency (RF) radiation is about to be implemented globally without investigating the risks to human health and the environment. This has created debate among concerned individuals in numerous countries. In an appeal to the European Union (EU) in September 2017, currently endorsed by >390 scientists and medical doctors, a moratorium on 5G deployment was requested until proper scientific evaluation of potential negative consequences has been conducted. This request has not been acknowledged by the EU. The evaluation of RF radiation health risks from 5G technology is ignored in a report by a government expert group in Switzerland and a recent publication from The International Commission on Non-Ionizing Radiation Protection. Conflicts of interest and ties to the industry seem to have contributed to the biased reports. The lack of proper unbiased risk evaluation of the 5G technology places populations at risk. Furthermore, there seems to be a cartel of individuals monopolizing evaluation committees, thus reinforcing the no-risk paradigm. We believe that this activity should qualify as scientific misconduct.

Introduction

Most politicians and other decision-makers using guidelines for exposure to radiofrequency (RF) radiation seem to ignore the risks to human health and the environment. The fact that the International Agency for Research on Cancer (IARC) at the World Health Organization (WHO) in May 2011 classified RF radiation in the frequency range of 30 kHz to 300 GHz to be a 'possible' human carcinogen, Group 2B (1,2), is being ignored. This has been recently exemplified in a hearing at the Tallinn Parliament in Estonia (3).

An important factor may be the influence on politicians by individuals and organizations with inborn conflicts of interests (COIs) and their own agenda in supporting the no-risk paradigm (4,5). The International Commission on Non-Ionizing Radiation Protection (ICNIRP) has repeatedly ignored scientific evidence on adverse effects of RF radiation to humans and the environment. Their guidelines for exposure are based solely on the thermal (heating) paradigm and were first published in ICNIRP 1998 (6), updated in ICNIRP 2009 (7) and have now been newly published in ICNIRP 2020 (8), with no change of concept, only relying on thermal effects from RF radiation on humans. The large amount of peer-reviewed science on non-thermal effects has been ignored in all ICNIRP evaluations (9,10). Additionally, ICNIRP has successfully maintained their obsolete guidelines worldwide.

COIs can be detrimental, and it is necessary to be as unbiased as possible when assessing health risks. There are three points that should be emphasized. Firstly, the evidence regarding health risks from environmental factors may not be unambiguous, and therefore informed judgements must be made. Furthermore, there are gaps in knowledge that call for experienced evaluations, and no conclusion can be reached without value judgements. Secondly, paradigms are defended against the evidence and against external assessments by social networks in the scientific community. Thirdly, the stronger the impact of decisions about health risks on economic, military and political interests, the stronger will stakeholders try to influence these decision processes.

Since the IARC evaluation in 2011 (1,2), the evidence on human cancer risks from RF radiation has been strengthened based on human cancer epidemiology reports (9-11), animal carcinogenicity studies (12-14) and experimental findings on oxidative mechanisms (15) and genotoxicity (16). Therefore, the IARC Category should be upgraded from Group 2B to Group 1, a human carcinogen (17).

The deployment of the fifth generation, 5G, of RF radiation is a major concern in numerous countries, with groups of citizens trying to implement a moratorium until thorough research

Correspondence to: Dr Lennart Hardell, The Environment and Cancer Research Foundation, Studievägen 35, SE-702 17 Örebro, Sweden

Key words: Switzerland, European Union, World Health Organization, International Commission on Non-Ionizing Radiation Protection, Scientific Committee on Emerging and Newly Identified Health Risks, Swedish Radiation Safety Authority, 5G, electromagnetic field, appeals, moratorium, microwave radiation, radiofrequency electromagnetic field, health risks, non-ionizing radiation guidelines, conflicts of interest

on adverse effects on human health and the environment has been performed. An appeal for a moratorium, currently signed by >390 international scientists and medical doctors, was sent to the European Union (EU) in September 2017 (18), currently with no EU response (19). Several regions have implemented a moratorium on the deployment of 5G motivated by the lack of studies on health effects, for instance Geneva (20).

In the present article, the current situation in Switzerland is discussed as an example (21). Additionally, the ICNIRP 2020 evaluation is discussed (8).

Evaluation of health risks in Switzerland

Several Swiss citizens have brought to our attention that Associate Professor Martin Röösli is the chair of two important government expert groups in Switzerland (directeur), despite possible COIs and a history of misrepresentation of science (22,23). These groups are Beratende Expertengruppe NIS (BERENIS; the Swiss advisory expert group on electromagnetic fields and non-ionizing radiation) (24), and the subgroup 3, the Mobile Communications and Radiation Working Group of the Department of the Environment, Transport, Energy and Communications/Eidgenössisches Departement für Umwelt, Verkehr, Energie und Kommunikation, evaluating RF-radiation health risks from 5G technology (25,26).

The conclusions made in the recent Swiss government 5G report are biased and can be found here (27,28). This 5G report concluded that there is an absence of short-term health impacts and an absence or insufficient evidence of long-term effects [see Table 17 (Tableau 17) on page 69 in the French version (27) and Table 17 (Tabelle 17) on page 67 in the German version (28)].

Furthermore, it was reported that there is limited evidence for glioma, neurilemmoma (schwannoma) and co-carcinogenic effects, and insufficient evidence for effects on children from prenatal exposure or from their own mobile phone use. Regarding cognitive effects, fetal development and fertility (sperm quality), the judgement was that the evidence on harmful effects is insufficient. These evaluations were strikingly similar to those of the ICNIRP (see Appendix B in ICNIRP 2020; 8). Other important endpoints, such as effects on blood-brain barrier, cell proliferation, apoptosis (programmed cell death), oxidative stress (reactive oxygen species) and gene and protein expression, were not evaluated.

According to Le Courrier November 19, 2019, Martin Röösli presented the conclusion in an interview in the following way: '*Sur l'aspect sanitaire pur, «le groupe de travail constate que, jusqu'à présent, aucun effet sanitaire n'a été prouvé de manière cohérente en dessous des valeurs limites d'immissions fixées», résume Martin Röösli, professeur d'épidémiologie environnementale à l'Institut tropical et de santé publique suisse*' (29). [*Regarding the health issue, the working group concludes that, until now, no health effect has been consistently proven below the given exposure limits, summarizes Martin Röösli, professor in environmental epidemiology at the Swiss Tropical and Public Health Institute*].

This Swiss evaluation is scientifically inaccurate and is in opposition to the opinion of numerous scientists in this field (18). In addition, 252 electromagnetic field (EMF) scientists from 43 countries, all with published peer-reviewed research on the biologic and health effects of nonionizing electromagnetic fields (RF-EMF) have stated that:

'*Numerous recent scientific publications have shown that RF-EMF affects living organisms at levels well below most international and national guidelines. Effects include increased cancer risk, cellular stress, increase in harmful free radicals, genetic damages, structural and functional changes of the reproductive system, learning and memory deficits, neurological disorders, and negative impacts on general well-being in humans. Damage goes well beyond the human race, as there is growing evidence of harmful effects to both plant and animal life*' (30).

We are concerned that the Swiss 5G report may be influenced by ties to mobile phone companies (COIs) by one or several members of the evaluating group.

COIs

Funding from telecom companies is an obvious COI. Martin Röösli has been a member of the board of the telecom funded Swiss Research Foundation for Electricity and Mobile Communication (FSM) organization and he has received funding from the same organization (31-33).

It should be noted that the FSM is a foundation that serves formally as an intermediate between industry and researchers. According to their website, among the five founders of FSM who '*provided the initial capital of the Foundation*' four are telecommunications companies: Swisscom, Salt, Sunrise, 3G Mobile (liquidated in 2011). The fifth founder is ETH Zurich (technology and engineering university). There are only two sponsors, Swisscom (telecommunications) and Swissgrid (energy), who '*support the FSM with annual donations that allow for both the management of the Foundation and research funding*' (34).

The same situation applies to being a member of ICNIRP (Table I) (35). In 2008, the Ethical Council at Karolinska Institute in Stockholm stated that being a member of ICNIRP is a potential COI. Such membership should always be declared. This verdict was based on activities by Anders Ahlbom in Sweden, at that time a member of ICNIRP, but is a general statement (2008-09-09; Dnr, 3753-2008-609). In summary: '*It is required that all parties clearly declare ties and other circumstances that may influence statements, so that decision makers and the public may be able to make solid conclusions and interpretations. AA [Anders Ahlbom] should thus declare his tie to ICNIRP whenever he makes statements on behalf of authorities and in other circumstances*' (translated into English).

COIs with links to industry are of great importance; these links may be direct or indirect funding for research, payment of travel expenses, participation in conferences and meetings, presentation of research, etc. Such circumstances are not always declared as exemplified above. A detailed description was recently presented for ICNIRP members (22).

ICNIRP

ICNIRP is a non-governmental organization (NGO) based in Germany. Members are selected via an internal process, and the organization lacks transparency and does not represent the

[a]WHO Observer in the main commission (95); [b]2002-2011; [c]2020-2024. The table is based on members of WHO, SCENIHR and SSM during the defined time period(s). No other individuals among those within WHO or SCENIHR were found in the list of SSM participants. A total of 15 additional experts in WHO were not members of SCENIHR, SSM or ICNIRP. SCENIHR, Scientific Committee on Emerging and Newly Identified Health Risks; SSM, Swedish Radiation Safety Authority; WHO, World Health Organization; EU, European Union; ICNIRP, International Commission on Non-Ionizing Radiation Protection.

opinion of the majority of the scientific community involved in research on health effects from RF radiation. Independent international EMF scientists in this research area have declared that: '*In 2009, the ICNIRP released a statement saying that it was reaffirming its 1998 guidelines, as in their opinion, the scientific literature published since that time has provided no evidence of any adverse effects below the basic restrictions and does not necessitate an immediate revision of its guidance on limiting exposure to high frequency electromagnetic fields. ICNIRP continues to the present day to make these assertions, in spite of growing scientific evidence to the contrary. It is our opinion that, because the ICNIRP guidelines do not cover long-term exposure and low-intensity effects, they are insufficient to protect public health*' (30).

ICNIRP only acknowledges thermal effects from RF radiation. Therefore, the large body of research on detrimental non-thermal effects is ignored. This was further discussed in a peer-reviewed scientific comment article (3).

In 2018, ICNIRP published '*ICNIRP Note: Critical Evaluation of Two Radiofrequency Electromagnetic Field Animal Carcinogenicity Studies Published in 2018*' (36). It is surprising that this note claims that the histopathological evaluation in the US National Toxicology Program (NTP) study on animals exposed to RF radiation was not blinded (12,13). In fact, unfounded critique of the NTP study had already been rebutted (37); however, this seems to have had little or no impact on this ICNIRP note casting doubt on the findings of the animal study: '*This commentary addresses several unfounded criticisms about the design and results of the NTP study that have been promoted to minimize the utility of the experimental data on RFR [radiofrequency radiation] for assessing human health risks. In contrast to those criticisms, an expert peer-review panel recently concluded that the NTP studies were well designed, and that the results demonstrated that both GSM- and CDMA-modulated RFR were carcinogenic to the heart (schwannomas) and brain (gliomas) of male rats*' (37).

In contrast to the opinion of the 13 ICNIRP commission members, the IARC advisory group of 29 scientists from 18 countries has recently stated that the cancer bioassay in experimental animals and mechanistic evidence warrants high priority re-evaluation of the RF radiation-induced carcinogenesis (38).

ICNIRP draft. On July 11, 2018, ICNIRP released a draft on guidelines (39) for limiting exposure to time-varying electric, magnetic and electromagnetic fields (100 kHz to 300 GHz). It was open for public consultations until October 9, 2018. Appendix B was based on assessment of health risks based on a literature survey (39).

Surprisingly, the IARC classification of RF-EMF exposure as Group 2B ('possibly' carcinogenic to humans) from 2011 was concealed in the background material to the new ICNIRP draft on guidelines. Notably, one of the ICNIRP commission members, Martin Röösli (40), was also one of the IARC experts evaluating the scientific RF carcinogenicity in May 2011 (41). He should be well aware of the IARC classification. The IARC classification contradicts the scientific basis for the ICNIRP guidelines, making novel guidelines necessary and providing a basis to halt the rollout of 5G technology.

Therefore, the ICNIRP provides scientifically inaccurate reviews for various governments. One issue is that only thermal (heating) effects from RF radiation are considered, and all non-thermal effects are dismissed. An analysis from the UK demonstrates these inaccuracies (4), also discussed in another article (5). All members of the ICNIRP commission are responsible for these biased statements that are not based on solid scientific evidence.

ICNIRP release of novel guidelines for RF radiation. On March 11, 2020, ICNIRP published their novel guidelines for exposure to EMFs in the range of 100 kHz to 300 GHz, thus including 5G (8). The experimental studies demonstrating a variety of non-thermal biological/health effects (9,10) are not considered, as in their previous guidelines (6,7). Additionally, the ICNIRP increased the reference levels for the general public averaged over 6 min for RF frequencies >2-6 GHz (those that will be used for 5G in this frequency range), from 10 W/m^2 (Tables 5 and 7 in ref. no. 6) to 40 W/m^2 (Table 6 in ref. no. 8), which paves the way for even higher exposure levels to 5G than the already extremely high ones.

Background dosimetry is discussed in Appendix A of the ICNIRP 2020 guidelines (8). The discussion on 'Relevant Biophysical Mechanisms' should be criticized. The only mechanism considered by ICNIRP is temperature rise, which may also occur with 5G exposure, apart from the established non-thermal biological/health effects (42,43). It is well known among experts in the EMF-bioeffects field that the recorded cellular effects, such as DNA damage, protein damage, chromosome damage and reproductive declines, and the vast majority of biological/health effects are not accompanied by any significant temperature rise in tissues (44-47). The ion forced-oscillation mechanism (48) should be referred to as a plausible non-thermal mechanism of irregular gating of electrosensitive ion channels on cell membranes, resulting in disruption of the cell electrochemical balance and initiating free radical release and oxidative stress in the cells, which in turn causes genetic damage (15,49). The irregular gating of ion channels on cell membranes is associated with changes in permeability of the cell membranes, which ICNIRP admits in its summary (8).

Health risks are discussed in Appendix B of the ICNIRP 2020 guidelines (8). Again, only thermal effects are considered, whereas literature on non-thermal health consequences is disregarded (9,10,50). In spite of public consultations on the draft, the final published version on health effects is virtually identical to the draft version, and comments seem to have been neglected (19). In the following section, Appendix B on health effects (8) is discussed.

Appendix B starts with: '*The World Health Organization (WHO) has undertaken an in-depth review of the literature on radiofrequency electromagnetic fields (EMFs) and health, which was released as a Public Consultation Environmental Health Criteria Document in 2014... Further, the Scientific Committee on Emerging and Newly Identified Health Risks (SCENIHR), a European Commission initiative, also produced a report on potential health effects of exposure to electromagnetic fields (SCENIHR 2015), and the Swedish Radiation Safety Authority (SSM) have produced several international reports regarding this issue (SSM 2015, 2016, 2018). Accordingly, the present guidelines have used these literature reviews as the basis for the health risk assessment associated with exposure to radiofrequency EMFs rather than providing another review of the individual studies*'.

In the last 11 years since its previous ICNIRP 2009 statement (7), ICNIRP has not managed to conduct a novel evaluation of health effects from RF radiation. However, as shown in Table I, several of the present ICNIRP members are also members of other committees, such as the EU Scientific Committee on Emerging and Newly Identified Health Risks (SCENIHR), the Swedish Radiation Safety Authority (SSM) and the WHO, thus creating a cartel of individuals known to propagate the ICNIRP paradigm on RF radiation (4,5,22,51). In fact, six of the seven expert members of the WHO, including Emelie van Deventer, were also included in ICNIRP (5,7). Therefore, Emilie van Deventer, the team leader of the Radiation Programme at WHO (the International EMF Project), is an observer on the main ICNIRP commission, and SSM seems to be influenced by ICNIRP. Among the current seven external experts (Danker-Hopfe, Dasenbrock, Huss, Harbo Polusen, van Rongen, Röösli and Scarfi), five are also members of ICNIRP, and van Deventer used to be part of SSM.

As discussed elsewhere (5), it is unlikely that a person's evaluation of health risks associated with exposure to RF radiation would differ depending on what group the person belongs to. Therefore, by selecting group members, the final outcome of the evaluation may already be predicted (no-risk paradigm). Additionally, we believe that this may compromise sound scientific code of conduct.

The SCENIHR report from 2015 (52) has been used to legitimate the further expansion of the wireless technology and has been the basis for its deployment in a number of countries. One method, applied in the SCENIHR report, to dismiss cancer risks involves the selective inclusion of studies, excluding studies reporting cancer risks and including some investigations with inferior epidemiological quality. The report has been heavily criticized by researchers with no COI (53): '*In January of 2015, the Scientific Committee on Emerging and Newly Identified Health Risks (SCENIHR) published its final opinion on (P)otential health effects of exposure to electromagnetic fields... SCENIHR has not answered the question it was appointed to investigate. The Committee has answered a* *different question, limiting its conclusions to whether certainty or causal effect is established, instead of possibility of health risks... Overall, SCENIHR has not conducted a scientific review process for judging possible health risks. This results in erroneous and deceptive conclusions by failing to conclude such possible health risks do exist. Evidence that SCENIHR has presented clearly and conclusively demonstrates that EMF health risks are possible, and in some cases are established. The Committee is obligated to draw to the attention of the European Commission that EMF is a new and emerging problem that may pose an actual or potential threat*'.

Regarding the SSM, only yearly updates are available and no overall evaluations are made. Therefore, no thorough review is presented. Over the years, the ICNIRP has dominated this committee (Table I). Therefore, it is unlikely that the opinion of the SSM will differ from that of the ICNIRP.

In 2014, the WHO launched a draft of a Monograph on RF fields and health for public comments (54). It should be noted that the WHO issued the following statement: '*This is a draft document for public consultation. Please do not quote or cite*'. ICNIRP completely ignored that request and used the aforementioned document. The public consultations on the draft document were dismissed and never published.

In addition to van Deventer, five of the six members (Mann, Feychting, Oftedal, van Rongen, and Scarfi) of the Core Group in charge of the WHO draft were also affiliated with ICNIRP, which constitutes a COI (Table I). Scarfi is a former member of ICNIRP (5). Several individuals and groups sent critical comments to the WHO on the numerous shortcomings in the draft of the Monograph on RF radiation. In general, the WHO never responded to these comments and it is unclear to what extent, if any, they were even considered. Nevertheless, the final version of the WHO 'in-depth review' has never been published. Instead, WHO made a call on October 8, 2019 (Emelie van Deventer), for systematic reviews to analyze and synthesize the available evidence: '*Through this Call, WHO invites eligible teams to indicate their interest in undertaking a systematic review on one (or more) of the following topics: SR1 - Effect of exposure to RF on cancer (human observational studies); SR2 - Effect of exposure to RF on cancer (animal studies); SR3 - Effect of exposure to RF on adverse reproductive outcomes (human observational studies); SR4 - Effect of exposure to RF on adverse reproductive outcomes (animal and in vitro studies); SR5 - Effect of exposure to RF on cognitive impairment (human observational studies; SR6 - Effect of exposure to RF on cognitive impairment (human experimental studies); SR7 - Effect of exposure to RF on symptoms (human observational studies); SR8 - Effect of exposure to RF on symptoms (human experimental studies; SR9 - Effect of exposure to RF on biomarkers of oxidative stress; SR10 - Effect of exposure to heat from any source and pain, burns, cataract and heat-related illness*'.

The authors of the present article were part of a team that applied to review SR1- human cancer. On December 20, 2019, the following reply was received from the WHO Radiation Programme: '*After careful review, we have decided to choose another team for this systematic review*'.

Transparency is of importance for the whole process. Therefore, a query was sent to the WHO requesting information regarding the following points: '*Who did the evaluation of the groups that answered the call? What criteria were applied? How many groups had submitted and who were these? Which groups were finally chosen for the different packages?*'. In spite of sending the request four times, January 2, January 3, April 7 and April 30, 2020, there has been no reply from WHO. This appears to be a secret process behind closed doors. These circumstances have also been reported in Microwave News (55).

It is important to comment on the current ICNIRP evaluation. Notably, on February 27, 2020, two weeks before the ICNIRP publication, the WHO Team on Public Health, Environmental and Social Determinants of Health issued a statement on 5G mobile networks and health: '*To date, and after much research performed, no adverse health effect has been causally linked with exposure to wireless technologies*' (56). This statement is not correct based on current knowledge (4,5,9-11,17,19) and was without a personal signature. The lack of research on 5G safety has been previously discussed (19). Furthermore, there is no evidence that can 'causally link' an adverse effect to an exposure. Causality is no empirical fact, it is an interpretation.

In the following section, only one (cancer) of the eight different end points in the ICNIRP publication (8) is discussed, since it deals with our main research area.

viii) Cancer.

'I*n summary, no effects of radiofrequency EMFs on the induction or development of cancer have been substantiated.*

Summary

The only substantiated adverse health effects caused by exposure to radiofrequency EMFs are nerve stimulation, changes in the permeability of cell membranes, and effects due to temperature elevation. There is no evidence of adverse health effects at exposure levels below the restriction levels in the ICNIRP (1998) guidelines and no evidence of an interaction mechanism that would predict that adverse health effects could occur due to radiofrequency EMF exposure below those restriction levels'.

Comments

The ICNIRP draft (39) has been previously described to some extent (19). The published final version on health effects is virtually similar to the draft. It cannot be taken at face value as scientific evidence of no risk from RF radiation. One example is the following statement (p. 41): '*...a set of case-control studies from the Hardell group in Sweden report significantly increased risks of both acoustic neuroma and malignant brain tumors already after less than five years since the start of mobile phone use, and at quite low levels of cumulative call time'.*

This allegation is not correct according to our publication for glioma (11). In the shortest latency group >1-5 years, the risk of glioma was not increased (odds ratio (OR), 1.1; 95% CI, 0.9-1.4) for use of wireless phones (mobile phone and/or cordless phone). There was a statistically significant increased risk of glioma per 100 h of cumulative use (OR, 1.011; 95% CI, 1.008-1.014) and per year of latency (OR, 1.032; 95% CI, 1.019-1.046) (11). These published results are in contrast to the ICNIRP claims.

Regarding acoustic neuroma, the corresponding detailed results are reported in our previous study (57). The shortest latency period >1-5 years yielded an OR of 1.2 (95% CI, 0.8-1.6) for use of wireless phones; the risk increased per 100 h of cumulative use (OR, 1.008; 95% CI, 1.002-1.014) and per year of latency (OR, 1.056; 95% CI, 1.029-1.085) (57). Therefore, the allegation by ICNIRP is false.

It is remarkable that ICNIRP is uninformed and that their writing is based on a misunderstanding of the peer-reviewed published articles as exemplified above. Additionally, our studies (11,57) and another study by Coureau *et al* (58), as well as the IARC evaluation from 2011 (1,2), are not included among the references. Several statements by ICNIRP are made without any scientific references. On the other hand, the Danish cohort study on mobile phone use (59) is included, in spite of the fact that it was judged by IARC (1,2), as well as in our review (60), to be uninformative. A biased article written by authors including ICNIRP members, used to 'prove' the no-risk paradigm for RF radiation carcinogenesis (23), is cited by ICNIRP. Notably, the article has not undergone relevant peer-review and we believe that it should not have been published in its current version. The shortcomings in the aforementioned article are discussed in the following sections. As discussed below, another claim (23) is incorrect regarding increased risk of brain tumors associated with use of wireless phones: '*However, they are not consistent with trends in brain cancer incidence rates from a large number of countries or regions, which have not found any increase in the incidence since mobile phones were introduced'.*

The criticism of the ICNIRP draft guidelines from 2018 by the EMF call (61) can also be applied to the current ICNIRP publication. The call has been signed by 164 scientists and medical doctors, as well as 95 NGOs: '*The International Commission on Non-Ionizing Radiation Protection (ICNIRP) issued draft Guidelines on 11th July 2018 for limiting exposure to electric, magnetic and electromagnetic fields (100 kHz to 300 GHz).1 These guidelines are unscientific, obsolete and do not represent an objective evaluation of the available science on effects from this form of radiation. They ignore the vast amount of scientific findings that clearly and convincingly show harmful effects at intensities well below ICNIRP guidelines.2 The guidelines are inadequate to protect humans and the environment. ICNIRP guidelines only protect against acute thermal effects from very short and intense exposure. The guidelines do not protect against harmful effects from low-intensity and long-term exposure, such as cancer, reproductive harm, or effects on the nervous system, although these effects are convincingly shown to appear from chronic exposure at intensities below ICNIRP limits.2,3*

ICNIRP's mandate to issue exposure guidelines needs to be seriously questioned. ICNIRP is not independent of industry ties as it claims.12,13 Its opinions are not objective, not representative of the body of scientific evidence, but are biased in favor of industry. It is obvious from their reluctance to consider scientific findings of harm that ICNIRP protects industry, not the public health, nor the environment.

We ask the United Nations, the World Health Organization, and all governments to support the development and consideration of medical guidelines16, that are independent of conflict of interests in terms of direct or indirect ties to industry, that represent the state of medical science, and that are truly protective'.

In the recent report on ICNIRP published by two Members of the European Parliament it is concluded: '*That is the most important conclusion of this report: For really independent scientific advice we cannot rely on ICNIRP. The European Commission and national governments, from countries like Germany, should stop funding ICNIRP. It is high time that the European Commission creates a new, public and fully independent advisory council on non-ionizing radiation'* (22).

Other examples of scientific misrepresentation

Published article. This section discusses an article with conclusions not substantiated by scientific evidence, representing a biased evaluation of cancer risks from mobile phone use and is an example of lack of objectivity and impartiality (23). The aforementioned report was used by ICNIRP 2020 (8) to validate that no risks have been found for brain and head tumors. Therefore, the article should be discussed in further detail.

The aforementioned article has numerous severe scientific deficiencies. One is that the results on use of cordless phones as a risk factor for brain tumors are not discussed. In fact, detailed results on cordless phones in studies by Hardell *et al* (11,57) are omitted.

When discussing glioma risk, all results on cumulative use of mobile phones, as well as ipsilateral or contralateral use associated with tumor localization in the brain, are omitted from the figures in the main text. Some results in the article by Röösli *et al* (23), such as cumulative use, can be found in the Supplementary Material, although the increased risk among heavy users is disregarded (11,57,58,62). In Supplementary Figure 4, all odds ratios regarding long-term (≥10 years) use of mobile phones are above unity (>1.0) for glioma and neuroma (23). No results are provided for ipsilateral mobile phone use (same side of tumor localization and mobile phone use), which is of large biological importance. Results on cumulative use, latency and ipsilateral use are especially important for risk assessment and have shown a consistent pattern of increased risk for brain and head tumors (11,57).

In the aforementioned article, recall bias is discussed as the reason for increased risk (23). The studies by Hardell *et al* (11,57) included all types of brain tumors. In one analysis, meningioma cases in the same study were used as the 'control' entity (11), and still a statistically significant increased risk of glioma was identified for mobile phone use (ipsilateral OR, 1.4; 95% CI, 1.1-1.8; contralateral OR, 1.0; 95% CI, 0.7-1.4) and for cordless phone use (ipsilateral OR, 1.4; 95% CI, 1.1-1.9; contralateral OR, 1.1; 95% CI, 0.8-1.6). If the results were 'explained' by recall bias, similar results would have been obtained for both glioma and meningioma. Thus, this type of analyses would not have yielded an increased glioma risk. Also, for acoustic neuroma a statistically significant increased risk was found using meningioma cases as 'controls' (57). Therefore, the results in the studies by Hardell *et al* (11,57) cannot be explained by a systematic difference in assessment of exposure between cases and controls. These important methodological findings were disregarded by Röösli *et al* (23).

In the analyses of long-term use of mobile phones, a Danish cohort study on mobile phone use is included (59), which was concluded to be uninformative in the 2011 IARC evaluation (1,2). A methodological shortcoming of the aforementioned study was that only private mobile phone subscribers in Denmark between 1982 and 1995 were included in the exposure group (59). The most exposed group, comprising 200,507 corporate users of mobile phones, were excluded and instead included in the unexposed control group consisting of the rest of the Danish population. Users with mobile phone subscription after 1995 were not included in the exposed group and were thus treated as unexposed at the time of cut-off of the follow up. No analysis of laterality of mobile phone use in relation to tumor localization was performed. Notably, this cohort study is now included in the risk calculations, although Martin Röösli was a member of the IARC evaluation group and should have been aware of the IARC decision. The numerous shortcomings in the Danish cohort study, discussed in detail in a peer-reviewed article (60), are omitted in the article by Röösli *et al* (23).

Regarding animal studies, a study by Falcioni *et al* (14) at the Ramazzini Institute on RF radiation carcinogenesis is only mentioned as a reference, but the results are not discussed. In fact, these findings (14) provide supportive evidence on the risk found in human epidemiology studies (3), as well as the results in the NTP study (12,13).

Furthermore, for incidence studies on brain tumors, the results are not presented in an adequate way. There is a lot of emphasis on the Swedish Cancer Register data (63,64), but the numerous shortcomings in the reporting of brain tumor cases to the register are not discussed. These shortcomings have been presented in detail in a previous study (63), but are disregarded by Röösli *et al* (23).

There is clear evidence from several countries regarding increasing numbers of patients with brain tumors, such as in Sweden (63,64), England (65), Denmark (66) and France (67).

The article by Röösli *et al* (23), does not represent an objective scientific evaluation of brain and head tumor risk associated with the use of wireless phones, and should thus be disregarded. By omitting results of biological relevance and including studies that have been judged to be uninformative, the authors come to the conclusion that there are no risks: '*In summary, current evidence from all available studies including in vitro, in vivo, and epidemiological studies does not indicate an association between MP [mobile phone] use and tumors developing from the most exposed organs and tissues'.*

Röösli *et al* (23), disregard the concordance of increased cancer risk in human epidemiology studies (11,57,58,62) animal studies (12-14,68,69) and laboratory studies (15,16,37). It is unfortunate that the review process of the aforementioned article has not been of adequate quality. Finally, there is no statement in the article of specific funding of this particular work, which is not acceptable. Only a limited number of comments on general funding are provided. It is not plausible that there was no funding for the study. We believe that, due to its numerous limitations, the aforementioned article should not have been published.

CEFALO. In 2011, a case-control study on mobile phone use and brain tumor risk among children and adolescents termed CEFALO was published (70). The study appears to have been designed to misrepresent the true risk, since the following question regarding cordless phone use was asked: '*How often did [child] speak on the cordless phone in the first 3 years he/she used it regularly?*'.

There are no scientific valid reasons to limit the investigation to the first 3 years. The result is a misrepresentation and a wrong exposure classification, since Aydin *et al* (70) willingly omitted any increase in the child's use of and exposure from cordless phone radiation after the first 3 years of use. This unscientific treatment of cordless phone exposure was not mentioned in the article other than in a footnote of a table and in the methods section (70); however, no explanation was provided: '*Specifically, we analyzed whether subjects ever used baby monitors near the head, ever used cordless phones, and the cumulative duration and number of calls with cordless phones in the first 3 years of use*'.

Since previous studies have demonstrated that these phone types, in addition to mobile phones, increase brain tumor risk (11,57), we believe that the exclusion of a complete exposure history on the use of cordless phones represents scientific misconduct.

In a critical comment the authors of the present study wrote: '*Further support of a true association was found in the results based on operator-recorded use for 62 cases and 101 controls, which for time since first subscription >2.8 years yielded OR 2.15 (95% CI 1.07-4.29) with a statistically significant trend (P = 0.001). The results based on such records would be judged to be more objective than face-to-face interviews, as in the study that clearly disclosed to the interviewer who was a case or a control. The authors disregarded these results on the grounds that there was no significant trend for operator data for the other variables - cumulative duration of subscriptions, cumulative duration of calls and cumulative number of calls. However, the statistical power in all the latter groups was lower since data was missing for about half of the cases and controls with operator-recorded use, which could very well explain the difference in the results*' (71).

Our conclusion was that: '*We consider that the data contain several indications of increased risk, despite low exposure, short latency period, and limitations in the study design, analyses and interpretation. The information certainly cannot be used as reassuring evidence against an association, for reasons that we discuss in this commentary*' (71).

This is in contrast to the authors that claimed that the study was reassuring of no risk in a press release from Martin Röösli, July 28, 2011: '*Kein erhöhtes Hirntumorrisiko bei Kindern und Jugendlichen wegen Handys... Die Resultate sind beruhigend*' ['*No increased brain tumour risk in children and adolescents for mobile phone users... The results are reassuring*'] (72).

A similar press release was issued by Maria Feychting at the Karolinska Institute in Stockholm stating: '*Reassuring results from first study on young mobile users and cancer risk... The so called CEFALO study does not show an increased brain tumor risk for young mobile users*' (73). Considering the results and the numerous scientific shortcomings in the study (70), the statements in these press releases are not correct.

Discussion

There is no doubt that several individuals included in Table I are influential, being members, as well as having consulting assignments, in several organizations, such as ICNIRP, BERENIS, the SSM, the Program Electromagnetic Fields and Health from ZonMw in the Netherlands, and the Rapid Response Group for the Japan EMF Information Center (74).

In fact, there appears to be a cartel of individuals working on this issue (75). Associate Professor Martin Röösli has had the chance to provide his view on the content of the present article relating to him. The only message from him was in an e-mail dated January 16, 2020: '*Just to be clear, all my research is funded by public money or not-for -profit fundations [foundations]. I think you will not help an important debate if you spread fake news*'. Obviously, as described in the present article, his comment is not correct considering his funding from the telecom industry (76,77).

As shown in Table I, few individuals, and mostly the same ones, are involved in different evaluations of health risks from RF radiation and will thus propagate the same views on the risks in agencies of different countries associated with the ICNIRP views (4,5). Therefore, it is unlikely that they will change their opinions when participating in different organizations. Furthermore, their competence in natural sciences, such as medicine, is often low or non-existent due to a lack of education in these disciplines (2). Therefore, any chance for solid evaluations of medical issues is hampered. Additionally, it must be concluded that if the 'thermal only' dogma is dismissed, this will have wide consequences for the whole wireless community, including permissions for base stations, regulations of the wireless technology and marketing, plans to roll out 5G, and it would therefore have a large impact on the industry. This may explain the resistance to acknowledge the risk by ICNIRP, EU, WHO, SSM and other agencies. However, the most important aspects to consider are human wellbeing and a healthy environment. Telecoms can make profit in a variety of ways, and wireless is just one of them. They have the capacity to maintain profits by using different techniques, such as optical fiber, that will provide more data with less RF radiation exposure. Particularly when considering the liability, they are incurring in their misguided insistence of wireless expansion that may ultimately catch up to them in the form of lawsuits, such as those previously experienced by asbestos and tobacco companies (78,79).

A recent book describes how deception is used to capture agencies and hijack science (80). There are certain tools that can be used for this. One is to re-analyze existing data using methods that are biased towards predetermined results (23). For example, this can be performed by hiring 'independent experts' to question scientific results and create doubt (81,82). As clearly discussed in a number of chapters of the books (80-82), front groups may be created to gain access to politicians and to influence the public with biased opinions. Other methods may involve intimidating and harassing independent scientists that report health risks based on sound science, or removing all funding from scientists who do not adhere to the no-risk pro-industry paradigm. Another tool would be economic support and courting decision makers with special information sessions that mislead them on science and mask bribery (3,5,19,80-82). An industry with precise marketing goals has a big advantage over a loose scientific community with little funding. Furthermore, access to regulatory agencies and overwhelming them with comments on proposed regulations is crucial (3). To counteract all these actions is time consuming and not always successful (19). Nevertheless, it is important that these circumstances are explored and published in the peer-reviewed literature as historical notes for future use.

Based on the Swiss and ICNIRP experiences, some recommendations can be made. One is to include only unbiased and experienced experts without COIs for evaluation of health risks from RF radiation. All countries should declare a moratorium on 5G until independent research, performed by scientists without any ties to the industry, confirms its safety or not. 2G, 3G, 4G and WiFi are also considered not to be safe, but 5G will be worse regarding harmful biological effects (42,83,84). The authors of the present article recommend an educational campaign to educate the public about the health risks of RF radiation exposure, and safe use of the technology, such as the deployment of wired internet in schools (85), as previously recommended by the European Council resolution 1815 in 2011 (86) and The EMF Scientist Appeal (87). Additionally, it is recommended that the government takes steps to markedly decrease the current exposure of the public to RF radiation, (88,89). Notably, DNA damage has been identified in peripheral blood lymphocytes using the comet assay technique, and in buccal cells using the micronucleus assay, in individuals exposed to RF radiation from base stations (90).

Finally, an alternative approach to the flawed ICNIRP safety standards may be the comprehensive work of the European Academy for Environmental Medicine (EUROPAEM) EMF working group that has resulted in safety recommendations, which are free from the ICNIRP shortcomings (50). Recently, the International Guidelines on Non-Ionising Radiation (IGNIR) have accepted EUROPAEM safety recommendations (91). The Bioinitiative group has recommended similar safety standards based on non-thermal EMF effects (92). WHO and all nations should adopt the EUROPAEM/Bioinitiative/IGNIR safety recommendations, supported by the majority of the scientific community, instead of the obsolete ICNIRP standards.

In conclusion, it is important that all experts evaluating scientific evidence and assessing health risks from RF radiation do not have COIs or bias. Being a member of ICNIRP and being funded by the industry directly, or through an industry-funded foundation, constitute clear COIs. Furthermore, it is recommended that the interpretation of results from studies on health effects of RF radiation should take sponsorship from the telecom or other industry into account. It is concluded that the ICNIRP has failed to conduct a comprehensive evaluation of health risks associated with RF radiation. The latest ICNIRP publication cannot be used for guidelines on this exposure.

Acknowledgements

The authors would like to thank Mr. Reza Ganjavi for valuable comments.

Funding

No funding was received.

Availability of data and materials

Data sharing is not applicable to this article, as no datasets were generated or analyzed during the present study.

Authors' contributions

LH and MC contributed to the conception, design and writing of the manuscript. Both authors read and approved the final manuscript.

Ethics approval and consent to participate

ABSTRACT

The radiofrequency electromagnetic radiation emitted by smart phones on biological systems has wide media coverage and public concern in recent years. The aim of this study was to explore the effects of fourth-generation cell phone radiation exposure on hematological (Total leukocyte count, Total erythrocyte count, and hemoglobin %), biochemical (Serum creatinine) parameters, and histopathological changes in the kidney and testis of Swiss albino mice. A total of 30 male Swiss albino mice weighing 45–65 g was randomly divided into three groups (n = 10). The first group A was the control group, the second group B, was exposed to 40 minutes of mobile phone radiation daily, the third group C was exposed to 60 minutes of radiation daily from two 2400 Megahertz fourth-generation connected mobile phones for 60 days, respectively. The electromagnetic radiation frequency radiometer measured the frequency of electromagnetic radiation emitted from cell phones. The specific absorption rate was calculated as 0.087 W/kg. The control group was kept under similar conditions, but the electromagnetic field was not given for the same period. All the mice were sacrificed at the end of the experiment. The blood samples were collected for hematobiochemical study, and then kidney and testis tissues were collected for histopathological study. Results of the study showed that the body weight and total erythrocyte count values were significantly ($p < 0.05$) decreased while total leukocyte count, hemoglobin %, and serum creatinine values were significantly ($p < 0.05$) increased in both the radiation exposure groups relative to the control group. Histopathological observation showed the kidney of 60 minutes exposed mice interstitial inflammation that causes marked mononuclear cellular infiltration compared to the 40 minutes and control mice. Compared to control mice, histopathological examinations of testicular tissue from the exposed mice, showed irregular in shapes and non-uniform sizes and fewer spermatogenic cells layer that leads to the larger lumen in the seminiferous tubules. It is concluded that fourth-generation cell phone radiation exposure may affect blood hemostasis and inflammation of mice's kidney and testis tissue. Based on these studies, it is important to increase public consciousness of potential adverse effects of mobile phone radiofrequency electromagnetic radiation exposure.

1. Introduction

Mobile phone use has dramatically increased over the last decade. Researchers had recommended that electromagnetic fields (EMF) released into the atmosphere from a mobile phone has deleterious effects on human beings (Azab, 2017; Elmas, 2016). At present mobile phones have started using fourth generation (4G) wireless communication technology (2200–2400 Megahertz (MHz)) that offer a very high internet speed. The adverse effects of EMF are a global public concern at present. Numerous adverse effects of cell phone use have been reported on different body organs such as the brain (Hardell et al., 2011; Kesari et al., 2011), ear (Colletti

1319-562X/

et al., 2011), and reproductive organs (Erogul et al., 2006; Falzone et al., 2011; Khillare and Behari, 1998). Many other studies have confirmed that the electromagnetic frequencies from mobile phone can cause numerous deleterious effects on molecular and cellular levels, such as DNA injury, various forms of cancer, oxidative stress, lipid peroxidation, increased free radicals, and chromosomal abnormalities (Akdag et al., 2016; Çam and Seyhan, 2012; Chauhan et al., 2017; Dasdag et al., 2015; Deshmukh et al., 2013; Megha et al., 2015). Blood parameters are the most significant way of assessing the state of health of animal models (Alghamdi and El-Ghazaly, 2012). EMF exposure from cell phones to humans contributes to reduced blood cells and an imbalance in plasma enzymes (Alghamdi and El-Ghazaly, 2012; Hasan and Issmer, 2014). In animal studies, long-term exposures to EMF can have detrimental effects on the liver, blood cells, and other activities. Hoverer, varying degrees of EMF have a conflicting influence on the blood and blood formation in animals (Sani et al., 2018; Usman et al., 2011). The impact of EMF in rats causes decreased hemoglobin oxygen-binding capacity; i.e., hypoxia does not exclude kidney damage contributions. It also has to be supposed that radiation influences hematopoiesis in the blood and bone marrow in the animals (Singh et al., 2004).

EMF has many biochemical consequences, such as the degradation of large cell molecules and ionic equilibrium imbalances. EMF exposure is associated with increased amounts of reactive oxygen species (ROS) formation (Kivrak et al., 2017). These ROS may cause injury to cellular constituents, including lipids, proteins, and DNA. Free radical generation may happen in various ways, such as UV light, immune response, radioactivity, stress, cigarettes, and physiological redox (Okano, 2008). It has been shown that electromagnetic radiation influences their impact on living organisms by producing or rising ROS. ROS leads to various physiological influences, such as DNA damage. Exposure to cell phone radiation oxidative stress (OS) has been increased in hematopoietic sites (Moustafa et al., 2001). The kidneys could absorb EMF from 900-MHz cell phones as, most of the time, they are carried by the belt (Oktem et al., 2005). Current concerns on mobile phone exposure are mainly focused on the kidney and testis. Because the mobile phone is usually kept in a pocket that is very close to the urogenital organ. The 2400 MHz 4G radiofrequency electromagnetic radiation (RF-EMR) has been exposed to male mice over a long period in this study.

The exposure of wireless electromagnetic radiation may injure both the hepatic, renal, and splenic tissues. Hasan and Islam (2020) reported that mononuclear cellular aggregates surrounding the bile duct and hepatic artery with congestion in the portal vein and the central vein of the liver after daily exposure of 4G connected 2400 MHz mobile phone radiation to mice whole-body for a month. With EMF exposure time, the amount of harm increased. The extent of potential harm expanded with the duration of EMF exposure (Lee et al., 2010).

Studies show that exposure to toxic chemicals, ionizing radiation, radiofrequency (RF) radiation, and other environmental nuisances are mainly related to male infertility (Bin-Meferij and El-Kott, 2015). In contrast, many studies have found that mobile phones have harmful effects on the male reproductive system (Kesari et al., 2011). EMF has probable harmful effects on male reproductive functions, specially Leydig cells, seminiferous tubules, and spermatozoa. The harmful effects of EMF on the male reproductive system based on the wave frequency and duration of exposure are the main factors (Kesari et al., 2011, 2010). Many cross-sectional experiments have already shown that cellular device usage may be related to semen quality, and increase cell phone use may cause male infertility (Ozguner et al., 2005; Pareek et al., 2005). (Lee et al. (2010) examined testicular histological changes in rats exposed to 848.5 MHz radiofrequency radiation (RFR) for 12 weeks. The possible adverse effects of mobile phone exposure on male fertility have been widely studied in the past decade by several researchers who have documented notable adverse effects of radiation on testis and seminal parameters, including motility, concentration and changes in testicular morphology, increased permeability of the blood-testis barrier, decreased sperm count, and percent normal morphology (Agarwal et al., 2008; Aitken et al., 2005; Fejes et al., 2005). Most mobile phone users bring their mobile phone in their pant pocket throughout the day that is very close to their genitals (Lavranos et al., 2012). Experiment results evaluated to identify testicular damages caused by low-intensity RF indicate contradictory findings (Dasdag et al., 1999; Ozguner et al., 2005; Ribeiro et al., 2007; Saunders and Kowalczuk, 1981; Yan et al., 2007). The leading cause associated with these adverse consequences was increased oxidative stress inside the reproductive organs (De Iuliis et al., 2009; Kesari et al., 2010; Mailankot et al., 2009; Naziroğlu et al., 2013; Qin et al., 2012). There has been a marked decrease in male fertility (Sepehrimanesh et al., 2014; Yildirim et al., 2015). Therefore, it is essential to evaluate the impact of RF-EMR on male fertility more reliably because men frequently carry mobile phones in their pockets, which is close to their reproductive organs.

Much of the previous research had already been conducted using second generation (2G) or third generation (3G) wireless mobile radiation exposure causes many physiological changes; however, no study has been undertaken using the 4G cell phone radiation (2200–2400 MHz) exposure in animal model. Besides this, mobile phone radiation can be consumed more by pelvic organs, particularly the kidney and testis, than many other inner organs. Therefore this experiment aimed to evaluate the impact of a 4G cell phone radiation exposure on hematobiochemical and possible histopathological effects on the kidney and testis of the Swiss albino mice model.

2. Materials and methods

2.1. Statement of the experiment

The research work was conducted in the Department of Anatomy and Histology, Faculty of Veterinary Science, Bangladesh Agricultural University, Mymensingh-2202, Bangladesh during the period from August 2018 to December 2019 to assess the impacts of 4G cell phone radiation on hematological (Total leukocyte count, Total erythrocyte count, and hemoglobin %), biochemical (Serum creatinine) parameters and histopathological changes in the kidney and testis of Swiss albino mice.

2.2. Ethical approval

As per the standardized instruction, all of the animals received human care. These research interventions have been permitted and carried out in compliance with animal welfare recommendations and use as defined by the Animal Welfare and Experimental Ethics Committee, Bangladesh Agricultural University, Mymensingh, Bangladesh (Protocol Number: AWEEC/BAU/2019-56).

2.3. Animals and experimental procedures

Swiss albino male mice (6 weeks old) (45 ± 65 g) have been obtained from the International Center for Diarrheal Disease Research (ICDDRB), Mohakhali, Dhaka. All the mice appeared to have good health and lacked any visible deformities. In the temperature-controlled environment, the mice were kept 52 cm × 36 cm × 25 cm in plastic cages. Daily diet and drink water ad libitum were given. After one week of acclimatization, the mice were haphazardly categorized into three equivalent groups; each group includes ten mice. The group named were A, B, and C. Individual weights of all mice were documented before radiation exposure. Among all of the three groups, group A has been considered controlled without radiation exposure. Group B was exposed to 40 min of radiation, and group C was exposed to 60 min of radiation from 4G cell phone connected handsets. Both experimental and operational requirements were designed to comply with the Care and Use of Laboratory Animals published by the U.S. National Institutes of Health.

2.4. The electromagnetic radiation exposure system

Two 2400 Megahertz (MHz) 4G connected mobile phones (Huawei GR5 2017) have been used for the generation of the radiofrequency electromagnetic radiation (RF-EMR) with different duration of exposure every day for 60 days (2 months). The cell phone with auto-answer mode was centrally installed on the roof of the mice cage from the inside for unified radiation exposure during the exposure time, trying to avoid contact with both animals and phones (Kumar et al., 2009; Narayanan et al., 2009). At first, we confirmed that there was no other source of electromagnetic fields (EMF). The temperature and humidity of the exposure room and the mouse cage were measured regularly during the RF-EMR application using a digital thermometer. When the mice were exposed to radiation, the frequency of RF-EMR emitted from cell phones was first measured by the electromagnetic radiation frequency radiometer (ED-78S Electrosmog frequency meter) in an active call using 2400 MHz range and assure that radiation exposure is uniformly distributed on the mice. The Specific absorption rate (SAR) was calculated as 0.087 W/kg. When the exposure begins, a call was made to the cell phone placed in the mice cage by another 4G connected 2400 MHz mobile phone and kept in answer mode for 40 and 60 min, respectively. During RF-EMR exposure, the mobile phone was held in the loudspeaker mode. Group B was exposed for 40 min per day hourly from 10.00 AM to 10.40 AM; Group C was exposed for 60 min, from 10.00 AM to 11.00 AM per day. The control group A was placed away from the radiofrequency source in the plastic cage. However, it was not receiving any exposure to radiation. This is similar to the exposure method used in previous studies for the 900-MHz RF-EMR application (Baş et al., 2013; Keleş et al., 2018; Odac et al., 2016; Odaci et al., 2015). That whole exposure time has been continued for two months.

2.5. Bodyweight

Each mouse's body weight was weighed using a digital scale at the beginning of the exposure to radiation and on the day of sacrificing.

2.6. Hematological analysis

The blood samples were obtained by sacrificing the mice at the end of the experiment. Approximately 1 ml of blood from the syringe was collected for hematological tests in the test tube containing anticoagulant Ethylene diamine tetraacetic acid (EDTA). The remaining amount of syringe blood has been used to obtain the serum. The below hematological variables were tested using Sysmex automated CBC analyzers: Total erythrocyte count (TEC), Hemoglobin (Hb) percentage (%), and Total leukocyte count (TLC).

2.7. Biochemical analysis

Approximately 2 ml of blood was obtained in a sterile glass test tube. The blood containing syringe was held upright at room temperature for 6 h. The tubes were then incubated in the refrigerator (4°C) overnight. Serum samples were isolated and centrifuged to eliminate excess blood cells where possible. Serum samples were deposited in the capped tube at −20°C for analysis of serum creatinine by using a CS-T240 auto-chemistry analyzer.

2.8. Sample collection for gross and histological study

Following blood collection, the kidney and testis were obtained for gross and histopathological inspection. Both kidneys and testis of different groups of mice were collected for the gross study. Parameters such as color and weight were taken into consideration for gross observation. The weight of the kidney and testis in the control group and the exposed group of mice were measured on a graded scale. After gross examination, samples were stored in 10% formaldehyde for 48 h. After processing to make paraffin blocks, 7 mm sections were cut using a rotary microtome (Leica RM2135) and stained with Haematoxylin & Eosin (H & E) stain for routine histological examination as per the proper procedure described by the (Zare et al., 2007).

2.9. Statistical analysis

The statistical analysis has been carried out using Graph pad prism software version 7.0 (GraphPad Software Inc., San Diego, CA). For statistical analysis One-way ANOVA followed by Turkeys Multiple Comparison Test was performed. A p-value <0.05 was considered to be statistically significant. Data were expressed as mean ± standard error (mean ± SEM).

3. Results

3.1. Effects on body weight

The mean body weight of mice in different groups has been presented in (Fig. 1A). The initial and final body weight of control mice was 25.36 ± 0.48 and 40.30 ± 0.21 g, respectively. In 40- and 60-minutes exposed mice, the mean body weight at the beginning of exposure and the end of the experiment were 26.47 ± 1.53, 28.74 ± 1.67 and 27.66 ± 1.65, 31.49 ± 0.89 g, respectively. After the end of the exposure, the body weight was significantly ($p < 0.05$) decreased in both exposed mice compared to the control mice.

3.2. Effects on hematological and biochemical parameters

The effects of mobile phone radiations on different hematological parameters, i.e., Total leukocyte count (TEC), Total erythrocyte count (TLC), and hemoglobin percentage (Hb%) in mice, were presented in (Fig. 1B). In the control mice, the mean value of TEC, TLC and Hb% were 7.23 ± 0.08, 5.81 ± 0.29 and 6.46 ± 0.13. The values of TLC and Hb% were increased significantly ($p < 0.05$) in 40 min (7.06 ± 0.13, 7.13 ± 0.31) and 60 min (7.87 ± 0.22, 7.76 ± 0.14) exposed mice compared to the control mice. In comparison to the 40 min exposed (6.70 ± 0.13) and control (7.23 ± 0.08) mice the values of TEC decreased significantly ($p < 0.05$) in 60 min (6.15 ± 0.27) exposed mice. The results of mobile phone radiations on Serum creatinine in different groups of mice were presented in (Fig. 1C). There was a significant increase ($p < 0.05$) in serum creatinine value in 40 min (0.80 ± 0.03) and 60 min (1.50 ± 0.06) exposed mice compared to the control mice (0.58 ± 0.06). Serum levels of creatinine indirectly reflect the kidney injury.

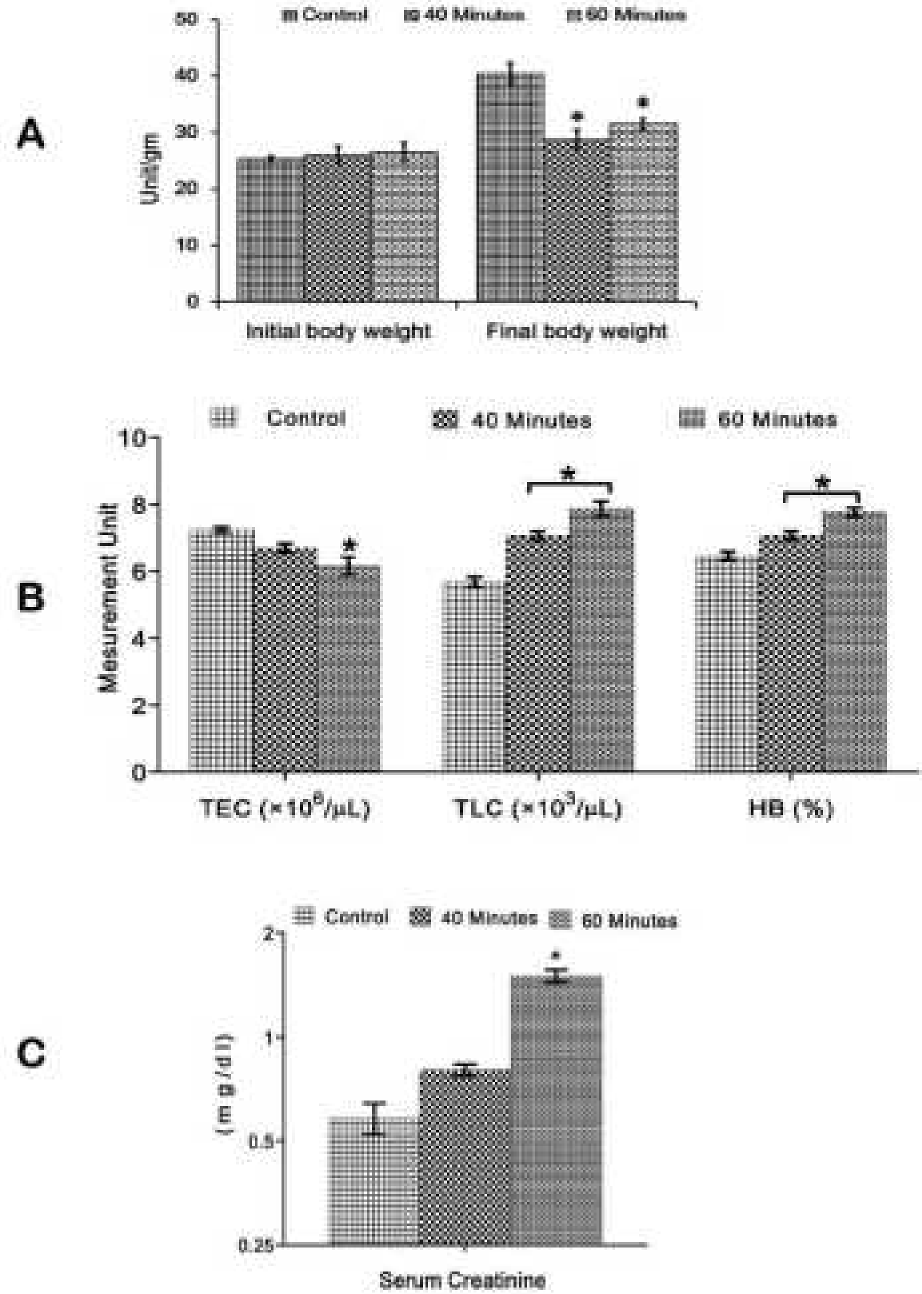

Fig. 1. (A) Initial and final body weight of different groups of mice. (B) Effects of mobile phone radiation on Total Erythrocyte Count (TEC), Total Leukocyte Count (TLC) and Hemoglobin (HB) % in mice. (C) Effects of mobile phone radiations on Serum creatinine in mice. Values were given as mean ± SE. *= Significant at 5% ($p < 0.01$) level of probability.

3.3. *Gross architectural change of the kidney and testis*

The kidney of control and 40 min exposed mice were reddish-brown with a smooth and shiny surface (Fig. 2A-B). No anatomical changes were found in these groups of mice while 60 min of the exposed mice showed pale colour on the kidney surface (Fig. 2C). The testis was white in colour, oval in shape in control and both exposed groups of mice. There were no morphological changes observed in control and exposed groups of mice (Fig. 2D-F).

3.4. *Histopathological study*

Examination of H & E-stained sections of the kidney collected from the control and 40 min exposed mice group revealed the normal histological architecture (Fig. 3A-B). Regarding the histopathological changes, the kidney of 60 min exposed mice showed interstitial inflammation that causes marked mononuclear cellular infiltration with severe vascular congestion in comparison to the control and 40 min exposed mice (Fig. 3C-F). Histopathological observations of the testes of control mice revealed the normal architecture of the seminiferous tubule. The seminiferous tubules were hexagonal or rounded and separated by a thin intertubular interstitial connective tissue. In the seminiferous tubules, the spermatogenic cells and the Sertoli cells were regularly arranged. Interstitium tissue contained the interstitial cells (Leydig cells). The Leydig cells seemed to be regular in form and size throughout the interstitial connective tissue between the seminiferous tubules. The germinal epithelia are formed of normal spermatogenic layers represented by spermatogonia, primary and secondary spermatocytes, spermatids and sperms. The spermatids are seen

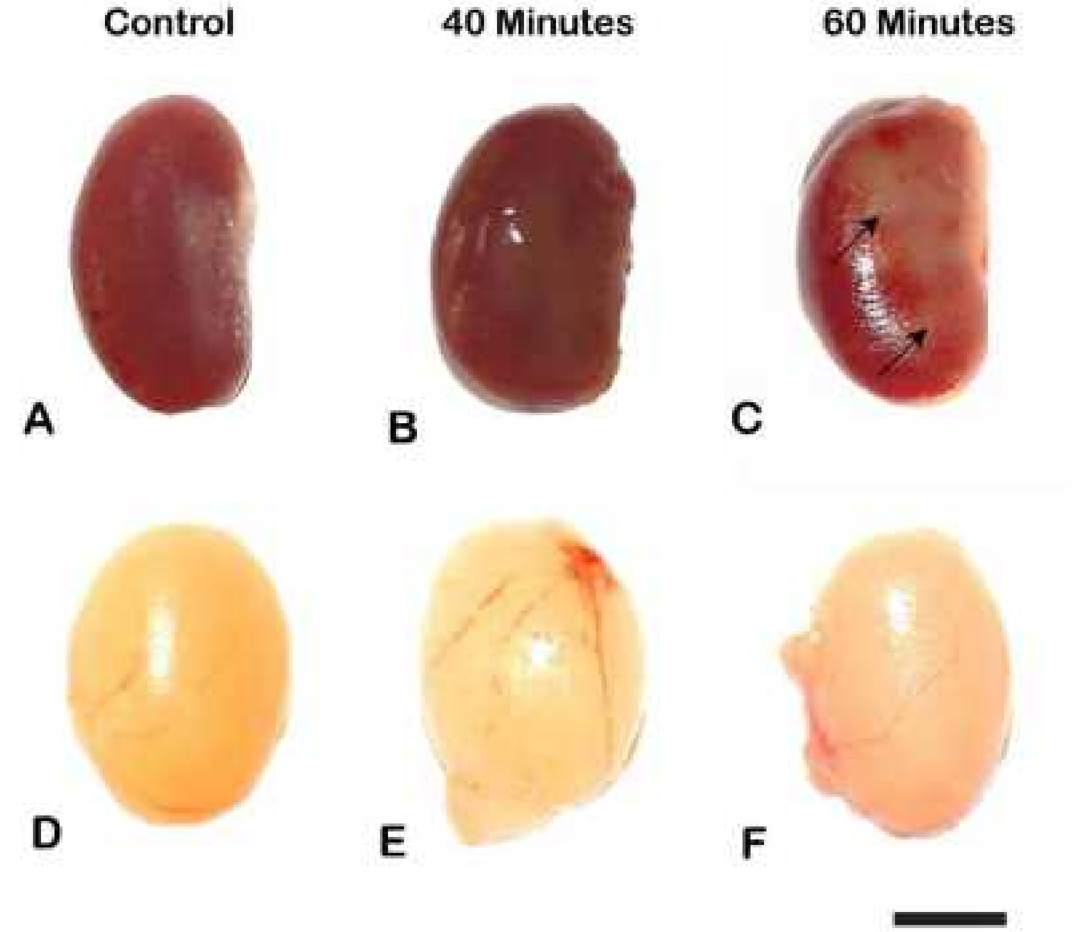

Fig. 2. Gross observation of the kidney of control (A), 40 min (B), and 60 min (C) exposed mice. Healthy appearance of the kidney was observed in control and 40 min exposed mice wherein 60 min exposed mice showed pale color (arrow) on the surface of the kidney; Gross observation of the testis of control (D), 40 min (E) and 60 min (F) exposed mice. Healthy morphological appearance of testis was found in control and exposed mice. Scale bar stands for 50 mm.

external to the spermatocytes. The spermatids then further develop into spermatozoa. They usually lie in groups with their heads projecting between the deeper cells and are connected with one of the Sertoli cells of the lining epithelium. The spermatogenic cells lines throughout different phases of growth and development were regularly arranged (Fig. 4A). The testis of 40 min exposed mice showed testicular atrophy and degenerative changes in spermatogenic cells lining the seminiferous tubules, with incomplete spermatogenesis. The seminiferous tubules were in a less regular shape. There was an alternation of the lining epithelium and reduced spermatogenic cells with a large lumen in the seminiferous tubules (Fig. 4B). The testis section of 60 min exposed mice revealed irregular shapes and non-uniform sizes seminiferous tubules. There were reduced spermatogenic cells with accumulation of spermatozoa in some of the seminiferous tubules, which were not seen in the control group. Occlusion of the lumen, as well as an increase in the size of seminiferous tubules, was evident (Fig. 4C-D). The mean height ofthe germinal epithelium was significantly decreased in both exposed groups. Testis lesions were more prominent in 60 min exposed mice in comparison with the testis of 40 min exposed mice (Fig. 4B-D).

4. Discussion

The harmful effects of mobile phone radiation exposure are poorly elucidated in vital organs such as the kidney and the testis. In the present study, therefore, we evaluated the effects of EMF on the hematobiochemical parameters and the potentially harmful effects of EMF on the kidneys and testis of mice model. Mobile phone users in various countries and continents are exposed to different frequencies. EMF exposure depends on the frequency of the cell phone (Meo et al., 2011). Many histological and biological experiments have been performed to assess the harmful effects of electromagnetic radiation on public health concerning the central nervous system, tumors, the renal system, fertility, growth, and immune function. The mice were exposed to 2400 MHz Radiofrequency Electromagnetic Radiation (RF-EMR) in this experiment because 2200–2400 MHz frequency 4G connected cell phones are extensively used in Bangladesh well as many other parts of the world. The present study results showed that the bodyweight of exposed mice was significantly reduced compared to the control mice, which agrees with the results of Wilson et al. (1999). The results (Shabat and Shahwan, 2017) noted that the mean weight of 3hrs and 5hrs high electromagnetic radiation (EMR) exposed groups decreases the initial mean weight. Likewise, (Marino et al., 1976) observed that mice exposed to low electric fields (150 V/cm) at 60 Hz for one month had reduced body weight and decreased water intake. Although (Lee et al., 2004) identified no significant weight difference in rats exposed to the magnetic field. (Gerardi et al., 2008) noted that the bodyweight increases as rats are exposed to electromagnetic radiation at a very well-defined frequency for a long-term duration.

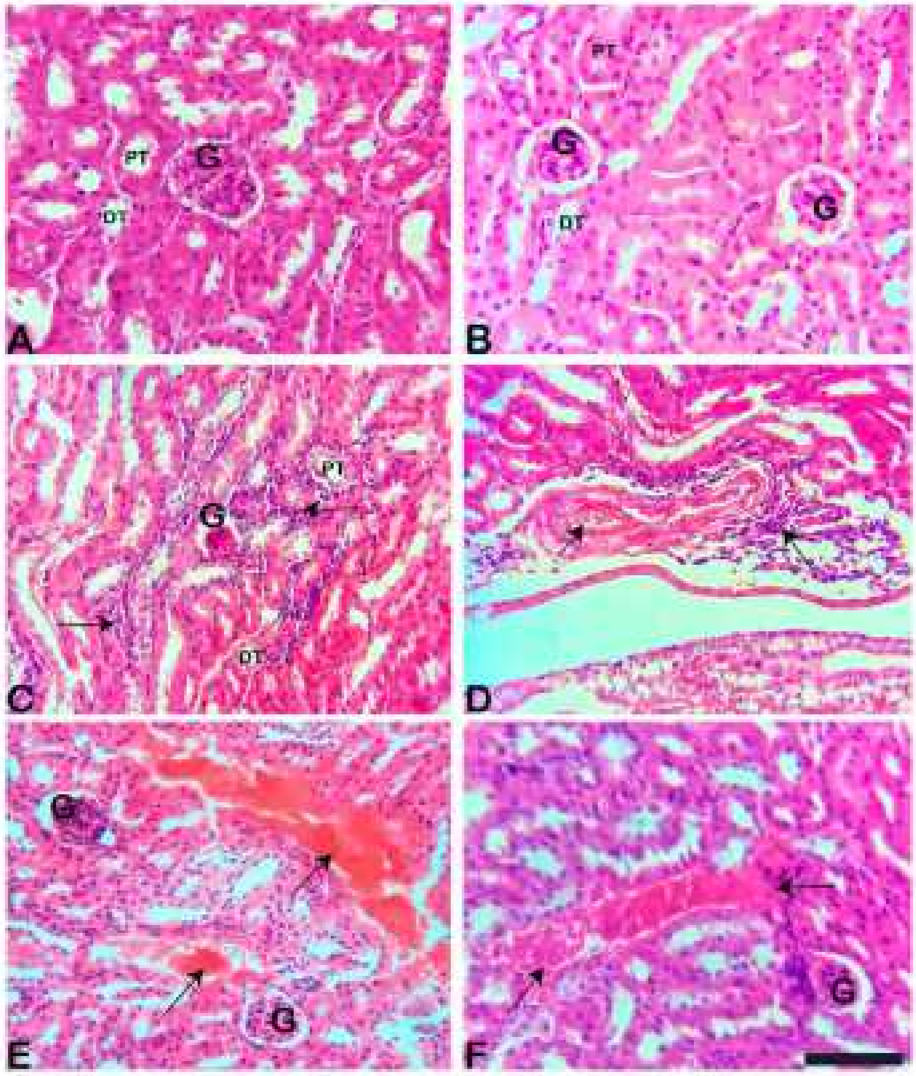

Fig. 3. Histological observation of the kidney of control (A), 40 min (B) & 60 min (C) exposed mice kidney sections stained with H & E stain. (A-B) showing control & 40 min exposure mice: no congestion, hemorrhage and normal architecture of renal corpuscles with their glomeruli and renal tubules were found in this group of mice; (C-F) exposure to 60 min: showing marked mononuclear cellular infiltration (arrow) with severe vascular congestion (arrow). Scale bar stands for 100 μm. G = Glomerulus, PT = Proximal Tubule & DT = Distal Tubule.

Changes in antioxidant, biochemical, enzymological, and hematological levels indicate weakening animal homeostasis leading to stress and a reduction in functional ability (Gecit et al., 2014; Saravanan et al., 2012). Assessments of blood parameters are the most important means to determine the health status of experimental animals (Sud and Sekhon, 1989). It helps in evaluating and recognizing the effects of EMF induced hazardous alterations to humans. The present study results revealed that mobile phone radiations affected the hematological profile of the test animals remarkably. There were significant increases TLC and Hb% in radiation-exposed groups compared to the control group. In this background, there is an increase in the concentration of Hb, RBC, WBC, and platelet numbers in rats following 1 h/day EMF exposure for 30 consecutive days has been shown (Amara et al., 2006; Salem et al., 2005). Previous epidemiological studies have shown an increased risk of leukemia due to both electric and magnetic fields (Bastuji-Garin et al., 1990; Garland et al., 1990). Our findings were similar to previous research in where shown that exposure to EMF has led to a noticeable rise in the number of WBCs and differential WBC counts (Alghamdi and El-Ghazaly, 2012; Amara et al., 2006; Aziz et al., 2010; Chater et al., 2006; Sisodia et al., 2013). The increase in TLC may be related to electromagnetic field exposure, which triggers the hemopoietic mechanism to discharge more white blood cells, which increases its number in blood circulation (Aziz et al., 2010; Sisodia et al., 2013). Our results comply with previous research done by Forgács et al. (2006) and Roberts et al. (1986) in which reports indicate that many hematological parameters such as white blood cell count, differential white blood cell count, platelet levels, red blood cell count, mitotic index of hematopoietic stem-cells, as well as hematocrit, hemoglobin and bone marrow megakaryocytes are susceptible to exposure to RF/Megawatt (MW). This suggests that these blood components are broken due to irradiation by electromagnetic radiation from cell phones. The TEC values of 60 min exposed mice were decreased significantly in compared to the control mice. Previous research studies stated that exposure to EMF in experimental models induced a reduction in RBCs' count and their correlations (Alghamdi and El-Ghazaly, 2012; Ghadhban and Mhaibes, 2018; Marzook et al., 2016; Sisodia et al., 2013). The reduction of the hematological parameters after exposure to EMF can be related to direct damage and excess production of reactive oxygen species (ROS) by association with electromagnetic radiation (Eid et al.,

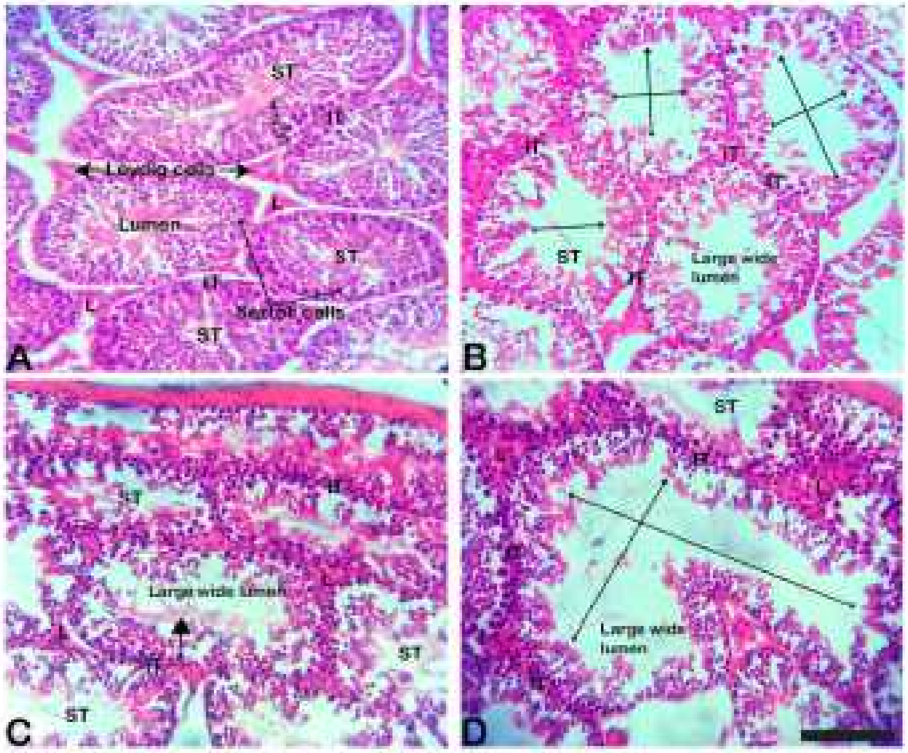

Fig. 4. Histological observation of testis of control (A), 40 min (B) & 60 min (C) exposed mice testis sections stained with H & E stain. The transverse section of the testis of (A) control mice showed normal seminiferous tubule. The seminiferous tubule has well-developed interstitial tissue, seminiferous tubeles lined with numerous Sertoli cells, and different stages of spermatogenic cells; (1) spermatogonia, (2) primary spermatocytes, (3) round secondary spermatocytes or early spermatids, and (4) spermatids. The Leydig cells were present between seminiferous tubules and seemed to be appropriate in both size and structure in the interstitial connective tissue. The testis of 40 min (B) exposed mice showing seminiferous tubules with irregular outlines, lost normal distribution of the epithelial lining, and fewer spermatogenic cells, which lead to the empty large wider tubule (large arrow) in the seminiferous tubules. The interstitium contains few Leydig cells compared to the control. (C-D) Testes of mice treated with 60 min EMR showed irregular shapes and non-uniform sizes of seminiferous tubules. There were reduced spermatogenic cells in the seminiferous tubules and accumulation of spermatozoa with exudate in the tubular lumen (arrowhead). The spermatogenic cells appeared pyknotic nuclei of some spermatogonia with degenerated spermatogenic cells, widening of the seminiferous tubular lumen (large arrow), and spermatozoa absence within the lumen. Scale bar stands for 100 µm. ST = Seminiferous Tubule, = Interstitial Tissue, L = Leydig cell.

2015; Sisodia et al., 2013). The free radicals affect the red blood cell membrane and cytoskeleton and leading to the leakage of hemoglobin from the cells (Creang et al., 2009; Eid et al., 2015). Red blood cell hemolysis reflects the degradation of cell integrity that can contribute to intracellular hemoglobin leakage (Eid et al., 2015). Spleen hyperfunction enhances red blood cell, leukocyte, and platelet breakdown rate. Due to hyperfunction of the spleen, the hematological variation has been happened in rats due to exposure to EMF was reported by Osbakken et al. (1986). The results revealed that the EMR waves damage the blood cell walls, leading to a decrease in the TLC count.

Besides, we also have investigated kidney dysfunction after exposure to EMF. Our study results indicated that the Serum creatinine value was significant increases in radiation exposed mice. Similarly, Tsuji et al. (1996) reported the increased blood urea nitrogen and creatinine levels in mice exposed to EMFs (5 T) for 48 h. Creatinine is generally created in muscles and exists freely in blood plasma and urine. Its higher serum levels act as an indicator of impaired renal function. This may be due to renal failure correlated with congestion in some tubules and focal leukocytic infiltration by pathological examination. Increased Serum creatinine levels in mice also agree with the findings of Asgari et al. (2014), who stated that Serum creatinine levels increased significantly in rats exposed to 3 h of mobile phone radiation a day compared to the control rats ($P < 0.01$). Studies have found that urea and creatinine increase dramatically when microwaving exposure duration increases (Morelli et al., 2005). Hepatic, renal, and splenic tissues were damaged due to exposure to electromagnetic radiation from cell phones (Al-Glaib et al., 2008). Damage to these tissues can lead to an increase in serum creatinine levels. There is a correlation between cell phone radiation and cellular damage that may contribute to elevated creatinine serum concentrations (Al-Glaib et al., 2008). Kidneys could mainly absorb the 900-MHz radiation from cell phones because they are often carried in the belt (Oktem et al., 2005), which may influence serum creatinine level.

There is a relation between mobile phone radiation and cellular damage that can lead to higher serum creatinine levels (Grundler et al., 1992). Grossly the kidney of control and 40 min exposed groups of mice were reddish-brown with a smooth and shiny surface. However, in 60 min exposed group showed pale color on the surface of the kidney. Our findings agreed with (Zare et al., 2007) that the morphology of the kidney of electromagnetic field exposed group mice was congested and pale. The testis was white in color and oval in shape in control and exposed mice.

The histopathological effects of 4G electromagnetic field radiation released from a cell phone device have been evaluated in this study by assessing the presence of pathological lesions in the kidney and testis. In the present study, there was no histological changes in the kidney of the control and 40 min exposed mice. In histopathological alterations, the 60-minute exposed mice reveals mononuclear cellular aggregates and intense venous congestion compared to the control mice. Similar findings were made by (Bayazit, 2009; Jaya et al., 2015; Makker et al., 2009; Ozguner et al., 2006) reporting that electromagnetic radiation (EMR) exposure induces many atrophied glomeruli, infiltration of leucocytes between the tubules of the kidney, and vacuolation of some tubules. Previous research found similar tissue changes using low frequencies EMR (Attia and Yehia, 2002; Forgács et al., 2004). Chauhan et al. (2017) stated that microwave radiation exposure causes shrunken glomeruli and irregular kidney tubules. Damage to these tissues may result in a rise in serum creatinine levels. EMR and high-power waves cause increased temperature rises. These waves interacted together and produced free radicals that cause increased lipid peroxidation and exhibit their damaging effects on cells like by ionizing rays. Free radicals damage the lipids of the cell and modify their composition and break protein boundary cause cell death. The oxidative stress induced by reactive oxygen species (ROS) is an essential element for tissue injury due to exposure to radiation (Al-Glaib et al., 2008; Markov, 2013).

Radiation is a potent toxicant, and exposure to the whole body may affect the animal's overall physiology and can have an effect on the normal histology and physiopathology of the testes (Sepehrimanesh et al., 2014). Radiation also has effects on steroidogenic and spermatogenic activity by the production of oxidative stress, antioxidant suppression mechanism, and various molecular processes included in decision-making about the death and life of germ cells that later changed normal testicular structure (Peltola et al., 1992). In the present experiment, histological examination of seminiferous tubules of irradiated mice showed marked pathological alterations in the form of shrinkage of tubules, distortion of cellular arrangement. These findings are in close agreement with the earlier report of (Goyal et al., 2011; Pareek et al., 2005), which documented the distorted architecture of seminiferous tubules in the form of shrunken tubules, pycnotic nuclei, necrotic cells, and degenerative effects of gamma rays on spermatogenesis in lethally irradiated mice.

In the present investigation, histological observation of testis of 40- and 60-minutes exposed mice showed that the seminiferous tubules were less regular in shape and alternation of the epithelium lining and fewer spermatogenic cells layer that led to the large wide lumen in the seminiferous tubules. There was an accumulation of spermatozoa and occlusion of the lumen in some of the seminiferous tubules. Similar findings were reported by Esa et al. (2018), who stated that the testicular tissue in mice exposed to a 3 kV EMF shows that the seminiferous tubules had almost the same size but less regular shape. EMF has caused noticeable changes in the seminiferous tubules in the testes of mice exposed to 5 kV contributing to uneven shapes and dimensions. Similar to the present study, Chauhan et al. (2017) stated that radiation-exposed group mice showed alternation of the epithelium lining of seminiferous tubules and occlusion of the lumen and size of seminiferous tubules was reduced with cell population. Several studies have shown that testis size and seminiferous tubules diameter were decreased following exposure to microwave radiation (Falzone et al., 2011; Ozguner et al., 2002). The excess free radical formation leads to histological and morphological changes in the testis and spermatogenic cell morphology. The ability of EMF to cause oxidative stress in the testes strongly suggests that the testis is a vulnerable tissue that is strongly dependent on oxygen for spermatogenesis and yet highly sensitive to the toxic effects of reactive oxygen enzymes (Chauhan et al., 2017; Dasdag et al., 1999). (Ozlem Nisbet et al., 2012) noticed that when rat exposure to electromagnetic radiation of 900–1800 MHz resulted in vacuolar degeneration, severe necrosis, and seminiferous epithelium desquamation. Long time exposure to 900 MHz EMF induced apoptosis of spermatogenic cells and responsible for reduced Leydig cell number as well assignificantly decreased mature spermatogenic cells and testosterone amount stated by many authors (Kim et al., 2014; 2009;; Sepehrimanesh et al., 2014). The present study revealed similar findings that there was a significantly decreased spermatogenic cell layer in radiation-exposed mice.

5. Conclusion

Cell phones are a fundamental part of our social lives. However, people are still worried about the potential effects of smartphones. In this study, we tended to focus mostly on the potentially harmful effects of 4G electromagnetic radiation from mobile phones. This study indicated that long-time exposure to mobile phone radiation could lead to degenerative changes on specific hematobiochemical parameters, including kidney and testis histology. The results indicate that kidney and testis were oxidative. Most reports concerning Electromagnetic effects with low frequency were concentrated at a specific organ or process. This study recommends that different vital organs are equally affected by similar bloodstream during high frequencies of EMF exposure due to excessive smartphone use. This research gives an insight into mobile emitted radiation that might induce alterations in the blood and the kidney and testis tissue. However, the study alerts us all to the potentially detrimental effects of long-term electromagnetic radiation exposure. To escape these harmful effects of cell phone radiation, excessive mobile phone use should be avoided. Hopefully, comprehensive long-term studies at the molecular level are undoubtedly required in order to draw definitive conclusions.

Declaration of Competing Interest

The authors declare that they have no known competing financial interests or personal relationships that could have appeared to influence the work reported in this paper.

Acknowledgements

We thank the Bangladesh Agricultural University Research System (BAURES) and University Grants Commission (UGC) of Bangladesh for providing financial support to conduct the research.

Funding

This work has been funded by the Bangladesh Agricultural University Research System (BAURES) Project (No. 2018/558AU-GC).

Author contributions

The experiment was planned and designed by MRI and IH. MRI has set up all the research facilities and supervised the entire research. IH conducted the entire laboratory works. IH participated in the histological analysis. IH with TA, MRA and MRI interpreted the findings of the statistical research activities and also engaged in the manuscript draft and carefully reviewed and revised the manuscript. The final version of the manuscript is read and agreed upon by all authors. Each author also guarantees that this contentor related information has not really been submitted to or will not be published anywhere.

Epigenetic modulations
Hippocampus
Wistar rat

ABSTRACT

Exponential increase in mobile phone uses, given rise to public concern regarding the alleged deleterious health hazards as a consequence of prolonged exposure. In 2018, the U.S. National toxicology program reported, two year toxicological studies for potential health hazards from exposure to cell phone radiations. Epigenetic modulations play a critical regulatory role in many cellular functions and pathological conditions. In this study, we assessed the dose-dependent and frequency-dependent epigenetic modulation (DNA and Histone methylation) in the hippocampus of Wistar rats. A Total of 96 male Wistar rats were segregated into 12 groups exposed to 900 MHz, 1800 MHz and 2450 MHz RF-MW at a specific absorption rate (SAR) of 5.84×10^{-4} W/kg, 5.94×10^{-4} W/kg and 6.4×10^{-4} W/kg respectively for 2 h per day for 1-month, 3-month and 6-month periods. At the end of the exposure duration, animals were sacrificed to collect the hippocampus. Global hippocampal DNA methylation and histone methylation were estimated by ELISA. However, DNA methylating enzymes, DNA methyltransferase1 (DNMT1) and histone methylating enzymes euchromatic histone methylthransferase1 (EHMT1) expression was evaluated by real-time PCR, as well as further validated with Western blot. Alteration in epigenetic modulation was observed in the hippocampus. Global DNA methylation was decreased and histone methylation was increased in the hippocampus. We observed that microwave exposure led to significant epigenetic modulations in the hippocampus with increasing frequency and duration of exposure. Microwave exposure with increasing frequency and exposure duration brings significant ($p < 0.05$) epigenetic modulations which alters gene expression in the hippocampus.

1. Introduction

Electromagnetic radiations are the fourth-largest and most rapidly increasing, the anthropogenic source of pollution on the earth. Globally wireless communication systems have increased tremendously in the last decade, which principally uses radiofrequency microwaves. The United States, National Toxicology Program (NTP), U.S. Dept. of Health and Human Services conducted two-year toxicology studies in rats and mice to elucidate potential health hazards from exposure to radiofrequency (700–2700 MHz). NTP reported evidence of cell phone signal exposure with tumors in the heart, brain and adrenal glands (https://ntp.niehs.nih.gov/whatwestudy/topics/cellphones/index.html). Different experimental studies in animal model also reported for, radiofrequency microwave-induced oxidative stress, DNA damage, enhanced neuronal loss, altered neurotransmitters, increased blood-brain barrier permeability and cognitive impairment (Dasdag and Akdag, 2016; Dasdag et al., 2009; Deshmukh et al., 2013b; Maskey et al., 2010; Mausset-Bonnefont et al., 2004; Megha et al., 2015b; Nittby et al., 2009; Pall, 2018; Salford et al., 2003). However, microwave exposed DNA damage also reported in different tissues in rat as well in human being (Akdag et al. 2016, 2018; Bektas et al., 2020). Various epidemiological studies in human too reported about MW radiation-induced increased brain glucose metabolism (Volkow et al., 2011), brain physiology, attention, reaction time, working memory (Schmid et al., 2012), systemic immune response (Kimata, 2005), glioma risk (Carlberg and Hardell, 2017). However, few studies in humans have been reported

about the insignificant effect of microwave radiation on human health (Elder et al., 2007; Hardell, 2017).

Hippocampus is a small curved part of the brain, located within the medial temporal lobe, and is well associated with learning, memory and spatial navigation. Higher polyunsaturated fatty acid content and metabolic rate as compared to other cells make neuronal cells more susceptible to molecular damage by different types of environmental stress as well as oxidative stress (Fritze et al., 1997; Hermann and Hossmann, 1997; Salim, 2017). Rich polyunsaturated fatty acid content makes neurons vulnerable to peroxidation due to the generation of ROS (Ferrante et al., 2017) and peroxidated fatty acids are well associated with neurodegeneration (Pratico, 2002). Mobile phone users constantly put their mobile in close contact with the head, therefore central nervous system (CNS) is the region primarily affected by MW radiation. ROS triggers oxidative stress in CNS (Salim, 2017) which could be a potent inducer of epigenetic modulation, responsible for cognitive dysfunctions.

Epigenetic modulations are the key regulators of gene expression without altering the genomic constitution. Intrinsic as well as extrinsic signals allow sustained changes in gene expression and allow an organism to adapt to its dynamic environment through modulated gene activity (Dauncey, 2012; Jaenisch and Bird, 2003; Mehler, 2008). DNA methyltransferase1 (DNMT1) transfers a methyl group to cytosine in genomic DNA, and responsible for the maintenance of methylation patterns (Chan et al., 2019). Whereas euchromatic histone methyltransferase1 (EHMT1) methylates histone H3 lysine-9 (H3K9), which brings transcriptional repression by modifying chromatin structure (Koemans et al., 2017). Disturbed methylation patterns of DNA and Histone associated with various pathological conditions including cancer, developmental abnormalities and cognitive functions (Chan et al., 2019; Koemans et al., 2017).

Increasing exposure to man-made electromagnetic radiation-induced changing environmental conditions is a threat to human health. Therefore, it is time to evaluate the impact of mobile phone signal radiation at genetic as well as epigenetic level. In an earlier study, we have reported about microwave-induced DNA damage (Deshmukh et al., 2016), reactive oxygen species (ROS) generation, oxidative stress (Deshmukh et al., 2013a) and ER-stress (Kumar et al., 2019) in rat brain. However, in neither study, we find any reports about microwave-induced epigenetic modulations in any experimental model, nor any study reported about the effect of microwave radiation on DNA/histone methylating enzymes (DNA methyltransferase1 and euchromatin histone methyltransferase1) expression in any experimental model. Therefore, the present study was designed to address the knowledge gap about microwave-induced epigenetic modifications and epigenotoxic nature of microwave, by evaluating the percentage of DNA/histone methylation and expression of DNA/histone methylating enzymes (DNMT1 and EHMT1) in the hippocampus following microwave exposure in male Wistar rat. In this study, we hypothesized that chronic microwave radiation may induce epigenetic changes in the form of altered DNA/histone methylation pattern, which disturb chromatin structure and transcription factors binding site in DNA, that could be responsible factor for microwave-induced carcinogenicity, reproductive toxicity, developmental abnormalities (Vornoli et al., 2019), and cognitive impairment (Deshmukh et al., 2015).

2. Methods

2.1. Experimental animal group

We obtained 96 male Wistar rats (100 ± 10 g) from the central animal house of the institute and randomly divided into 12 groups (Sham exposed, 900 MHz, 1800 MHz and 2450 MHz, each for one-month, three-month and six-month respectively), and animals were placed in galvanized wired cages. They were made familiarized to laboratory conditions for 7 days and kept under standard conditions (Humidity 40–50% and temperature 22 ± 2 °C) with 12-h light and dark cycle. Nutritionally adequate diet from Nutri-lab (Bengaluru, India) and water provided *ad-libitum.* Rats were divided into 12 groups as shown in supplementary table 1.

This study and protocol were approved by the Institutional Animal Ethical Committee, UCMS & GTB hospital (University of Delhi), Dilshad Garden, Delhi-110095 **(UCMS/IAEC/2016/093)**. Care of animals was undertaken as per guidelines suggested by the committee for the purpose of control and supervision of experiments on animals (CPCSEA), Govt. of India.

2.2. Microwave exposure system

Male Wistar rats were exposed to RF-MW under the gigahertz electromagnetic (GTEM) cell. The schematic diagram of the microwave exposure system with a signal generator and GTEM cell (Supplementary figure 1). RF-MW exposure system was designed with the help of the Centre for Applied Research in Electronics (CARE) at the Indian Institute of Technology, New Delhi, India. For uniformity of the electric field, the system was calibrated and experimentally validated before animal exposure by an E-Field probe (Rohde & Schwarz NRV-Z32, Germany). RF-MW exposure was operated in well-controlled temperature and lighting conditions.

Sham exposed animal groups were control groups, which were kept under the same conditions and duration of time without any exposure to RF-MW. Each group of rats was given whole body RF-MW exposure in GTEM cell (Amitec Electronics Ltd., India), kept 1 m away from the signal input port, at defined frequency of 900 MHz, 1800 MHz, and 2450 MHz, and SAR of 5.84×10^{-4} W/kg, 5.94×10^{-4} W/kg and 6.4×10^{-4} W/kg respectively by the established power balance method as suggested by Ardoino et al., (2005), as shown above in Table 1 (supplementary data) at power level 1 mW for 2 h per day for one-month, three-month and six-month. For Specific Absorbance Rate (SAR) measurement representative rats with 106 g average weight was used, and SAR was calculated by power balance method using following equation:

$$P_{abs}/rat = 1/n\ (P_{in} - P_{out} - P_{refl})$$

Where, P_{abs} = Radio frequency (RF) power in watt absorbed per animal, n = number of animals within the cell, P_{in} = input power (Watt), P_{out} = output power (Watt) and P_{refl} = reflected power (Watt).

2.3. Expression of DNA methyltransferases and histone methyltransferases

Immediately after completion of each specified duration (1-month, 3-month, and 6-month) for RF-MW exposure, animals were decapitated and the hippocampus was isolated from the brain. Total RNA was extracted from the hippocampus using TRIzol reagent (Life Technologies, USA) as per the manufacturer's given protocol. One microgram of total RNA was converted into cDNA with an iScript cDNA synthesis kit (Bio-Rad, USA) as suggested by the manufacturer. Further RT-PCR (qRT-PCR) was performed in 20 μl vol. with SsoFast Eva Green supermix (Bio-Rad, USA) on CFX Connect™ Real-Time PCR (Bio-Rad, USA) with primers listed in Table 1. Each sample was run in triplicate and the relative fold change of selected genes was calculated by the comparative $2^{-\Delta\Delta}$Ct method (Livak and Schmittgen, 2001).

Table 1
Primer sequences used for qRT-PCR.

Gene	Forward primer (5′-3′)	Reverse primer (5′-3′)
DNMT1	GAGGCACTGTCCGTCTTTGA	CTGATTGATTGGCCCCAGGT
EHMT1	TGGATTCCCTGGATCTCCGT	GCACCAAGAGTGGTGCTTTG
GAPDH	TGCCCCCATGTTTGTGATG	TGGTGGTGCAGGATGCATT

2.4. Western-blotting of ER-stress associated transcription factor

Total proteins were extracted from the hippocampus of the male Wistar rat by using TRIS-NaCl buffer, immediately after decapitation and western blots were performed as suggested by Mahmood and Yang, (2012). Briefly, samples with 50 ng of protein were loaded onto 10% polyacrylamide gel with 0.1% SDS and separated by electrophoresis at 100 V for 180 min. Proteins were then transferred onto PVDF membrane and blocked with 5% BSA for 1 h. Primary antibody against DNMT1 and EHMT1, protein at 1:1000 (Signal way antibody, USA) was added next and left overnight at 4 °C. After washing with PBST, membranes were incubated with secondary HRP conjugated antibodies for 2 h and after washing with PBST again, proteins were visualized with ECL reagents (Bio-Rad, USA) on chemidock (My ECL imager, Thermo, USA). The bands were analyzed with Kodak ID image analysis software. All band intensities were normalized to β-actin.

2.5. 5-Methylcytosine DNA ELISA

Genomic DNA was isolated from the hippocampus of the rat brain by using spin column method as per the manufacturer's protocol (Promega DNA isolation kit, USA). Global percentage DNA methylation was estimated by measuring 5-methylcytosine (5-mC), using a 5-mC DNA ELISA kit (Zymo Research, USA), as per manufacturer's protocol. Briefly, 100 ng of isolated genomic DNA along with positive and negative controls of double-stranded DNA (provided with the kit) was denatured and used to coat the wells of microtitre plate with given coating buffer. All standards and hippocampal DNA were assayed in duplicate. Anti-5-mC antibody and HRP conjugated secondary antibody used for colour development. Absorbance measured at 405 nm and the percentage of 5-mC DNA calculated by using a second-order regression equation.

2.6. Histone H3K9 methylation

Histone protein isolation and assessment of their methylation from the hippocampus of the rat brain were performed by using a Histone H3K9 methylation assay kit (Epigentek, EpiQuik Global Histone H3K9 Methylation Assay) as per manufacturer's protocol. Extracted histone protein of 200 ng/μl was used for the evaluation of histone methylation percentage as suggested by the manufacturer. The percentage of H3K9 methylation was measured by using the standard curve, which was plotted with positive and negative control run along with the extracted histone protein.

2.7. Statistical analysis

Statistical analysis was carried out at SPSS (IBM SPSS statistics version 25) and values were expressed as mean ± SD (standard deviation). The significance of difference among the group was determined by a one-way analysis of variance (ANOVA) followed by Pearson's correlations and Tukey's post hoc test. Statistical significance was accepted at $p < 0.05$.

3. Result

DNA methyltransferases1 (DNMT1) and euchromatic histone methyltransferase1 (EHMT1) gene expression were evaluated by quantitative real-time PCR, in all specified groups of rats in Table 1. DNA methyltransferases1 and euchromatic histone methyltransferase1 have a crucial role in DNA and histone methylation respectively. In the present study, the expression of the *Dnmt1* gene was decreased, however, the *Ehmt* gene was increased in microwave exposed rat groups, with respect to sham exposed rat groups (Fig. 1A and 2A).

To validate the gene expression pattern of qRT-PCR, the expression levels of DNMT1 and EHMT1 further analyzed by Western blot by using a respective antibody, anti-DNMT1 antibody and anti-EHMT1 antibody (Signalway antibody, USA) in the hippocampal cell lysates. The Western blot analysis also indicated that expression of DNMT1 decreased and EHMT1 increased, with increasing frequency and duration of exposure (Fig. 1B and C, Fig. 2B and C).

3.1. EHMT1 expression

Expression of *Ehmt1* mRNA was increased with increasing microwave exposure frequency as 1.17-fold in 900 MHz, 1.29-fold in 1800 MHz and 1.63-fold in the 2450 MHz exposure group when compared with the sham-exposed group (Fig. 1A). In post hoc analysis, the difference was found significant ($p < 0.05$) when the sham-exposed group was compared with 900 MHz, 1800 MHz, and 2450 MHz exposure groups. When we compared the 900 MHz with 2450 MHz and the 1800 MHz with the 2450 MHz exposure group, we again noticed a significant ($p < 0.05$) change. However, 900 MHz and 1800 MHz exposed groups did not show any significant differences between each other.

After three-month of exposure, significant ($p < 0.05$) upregulation of *Ehmt1* mRNA expression in the hippocampus was noticed. After the 3-month exposure gene expression increases, 1.32-fold in 900 MHz, 1.40-fold in 1800 MHz and 1.70-fold in 2450 MHz frequency exposed group when compared to sham-exposed group respectively (Fig. 1A). We also observed a higher fold change in the three-month exposure group at the respective frequency. In the post hoc test, a significant ($p < 0.05$) increase in fold change was observed when the sham-exposed group was compared with 1800 MHz and 2540 MHz exposure frequency. The 900 MHz group and 2450 MHz group show a significant difference, but no significant difference in fold change was observed when we compared 900 MHz with 1800 MHz and 1800 MHz with 2450 MHz.

Similarly, in the six-month exposure group, significant ($p < 0.05$) upregulation of *Ehmt1* mRNA expression in the hippocampus of rat brain was also observed with increasing microwave exposure frequency, 1.6-fold in 900 MHz, 1.75-fold in 1800 MHz and 2.32-fold increase in 2450 MHz microwave exposure group with respect to sham-exposed group respectively (Fig. 1A). In the six-month exposure group, we observed greater fold change with respect to the three-month and one-month exposure group at respective frequency. Post hoc test, shown significant ($p < 0.05$) increase in fold change was noticed with respect to the sham-exposed group. The significant difference of fold change was obtained when we compared 900 MHz frequency fold change with 2450 MHz frequency and 1800 MHz frequency fold change with the 2450 MHz frequency fold change. However, no significant difference was found when we compared 900 MHz fold change with 1800 MHz fold change.

The gene expression profile was validated with Western blot analysis of EHMT1 protein (Fig. 1B). Data were normalized with housekeeping protein β-actin shown in the bar diagram (Fig. 1C). In post hoc analysis all the changed expression was found significant ($p < 0.05$).

3.2. DNMT1 expression

Expression of *Dnmt1* mRNA after one month was 0.71-fold downregulated in 900 MHz, 0.57-fold downregulated in 1800 MHz and 0.39-fold downregulated in the 2450 MHz exposure group (Fig. 2A). Post hoc analysis was found significant ($p < 0.05$) when we compared 900 MHz with 2450 MHz and 1800 MHz with a 2450 MHz exposure group. However, 900 MHz and 1800 MHz exposed groups did not show significant downregulation when compared with each other.

Significant ($p < 0.05$) downregulation of *Dnmt1*mRNA expression in the hippocampus was noticed. Gene expression decreases with increasing microwave exposure frequency 0.67-fold in 900 MHz, 0.53-fold in 1800 MHz and 0.37-fold in 2450 MHz frequency exposed group when compared to sham-exposed group respectively (Fig. 2A). Following three-month exposure, we observed more downregulation in gene expression with respect to one-month exposure at respective frequency. Significant ($p < 0.05$) decrease in fold change was observed

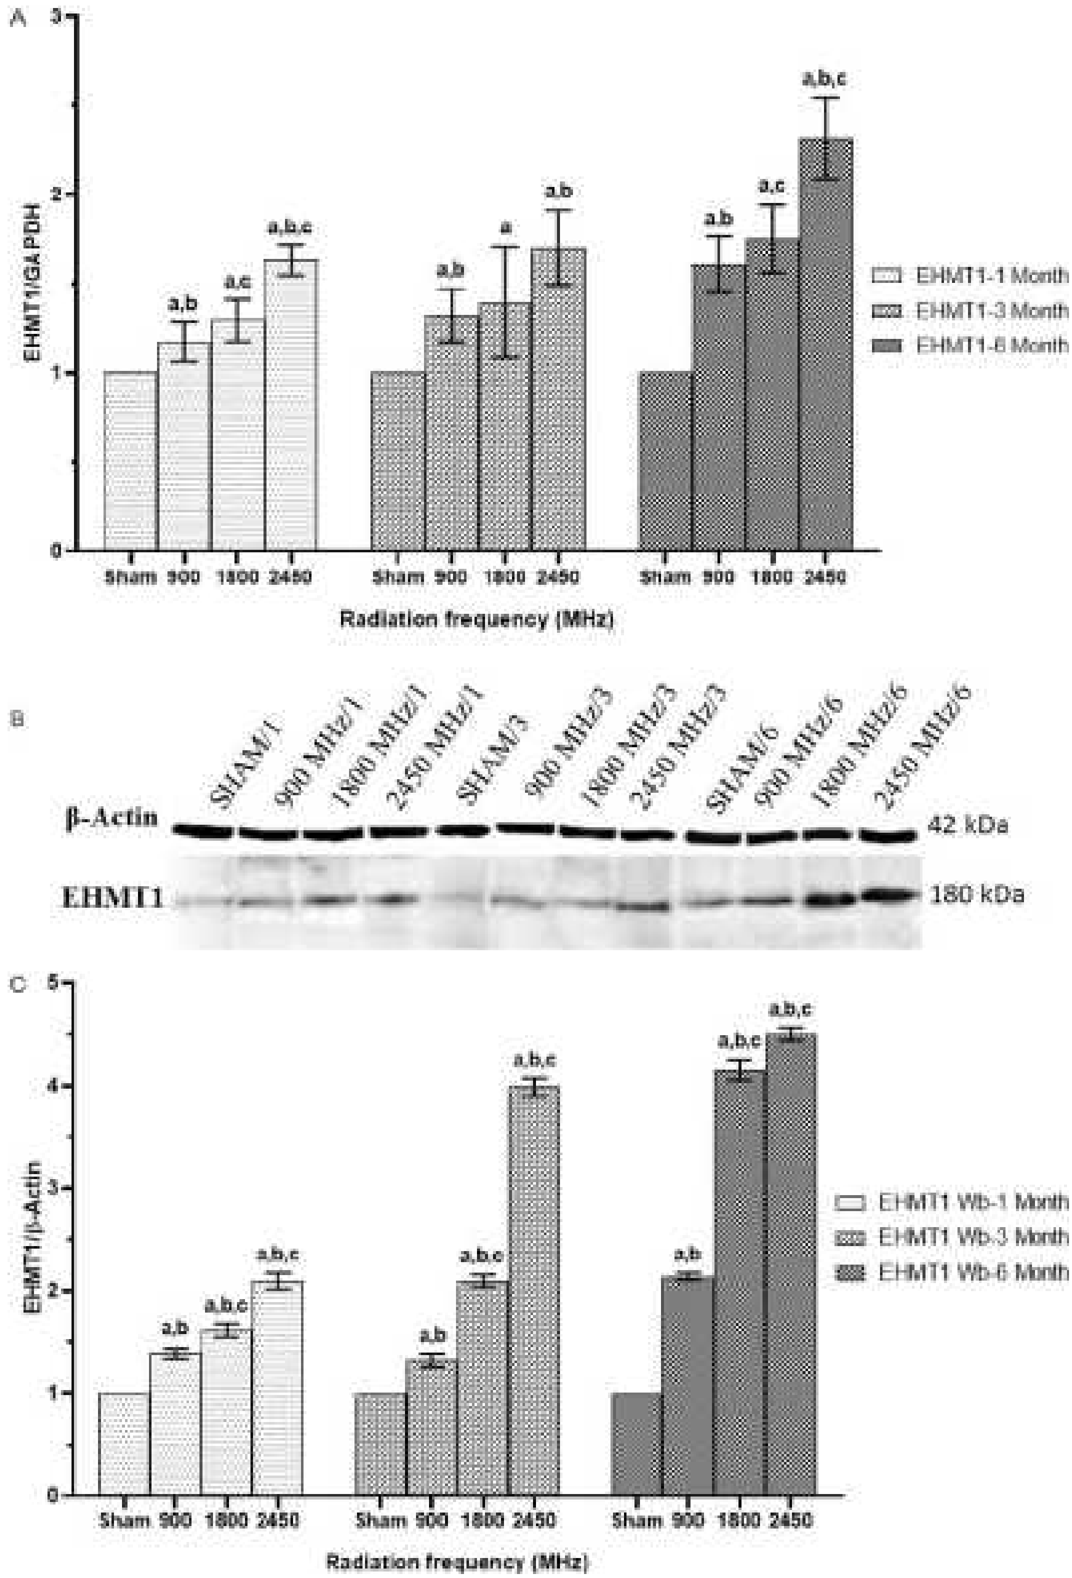

Fig. 1. (A) Effect of microwave exposure on *Ehmt1* gene expression in rat brain. The relative transcription levels of euchromatic histone methyltransferase1 (EHMT1) in the hippocampus of Wistar rat in response to radiofrequency microwave exposure for one-month, three-month and six-month. Total RNA was extracted from the hippocampus of sham-exposed and microwave exposed Wistar rats and was analyzed by quantitative real-time PCR to deduce the expression level of *Ehmt1* genes. The expressional value of the hippocampus of the microwave exposed Wistar rat were normalized to those of sham-exposed rat. The relative transcriptional values of the *Ehmt1* gene were calculated by normalizing to the GAPDH expression using $2^{-\Delta\Delta Ct}$ (n = 8) method and we found its increasing as with increasing frequency and exposure duration. (B) Western blot of Ehmt1 in the hippocampus of Wistar rat after one-month, three-month and six-month microwave exposure at 900, 1800 and 2450 MHz frequency. (C) Band intensity of Western blot was quantified by dosimetry, and the protein level was normalized relative to β-actin which was shown in the bar diagram. Each bar represents the mean value with ±SD of experiments in triplicates. Statistical significance value accepted in a two-tailed *t*-test, if $p < 0.05$. Respective p-value *a,b,c significantly different from respective control (p < 0.05) calculated by one way ANOVA followed by Tukey's test.*

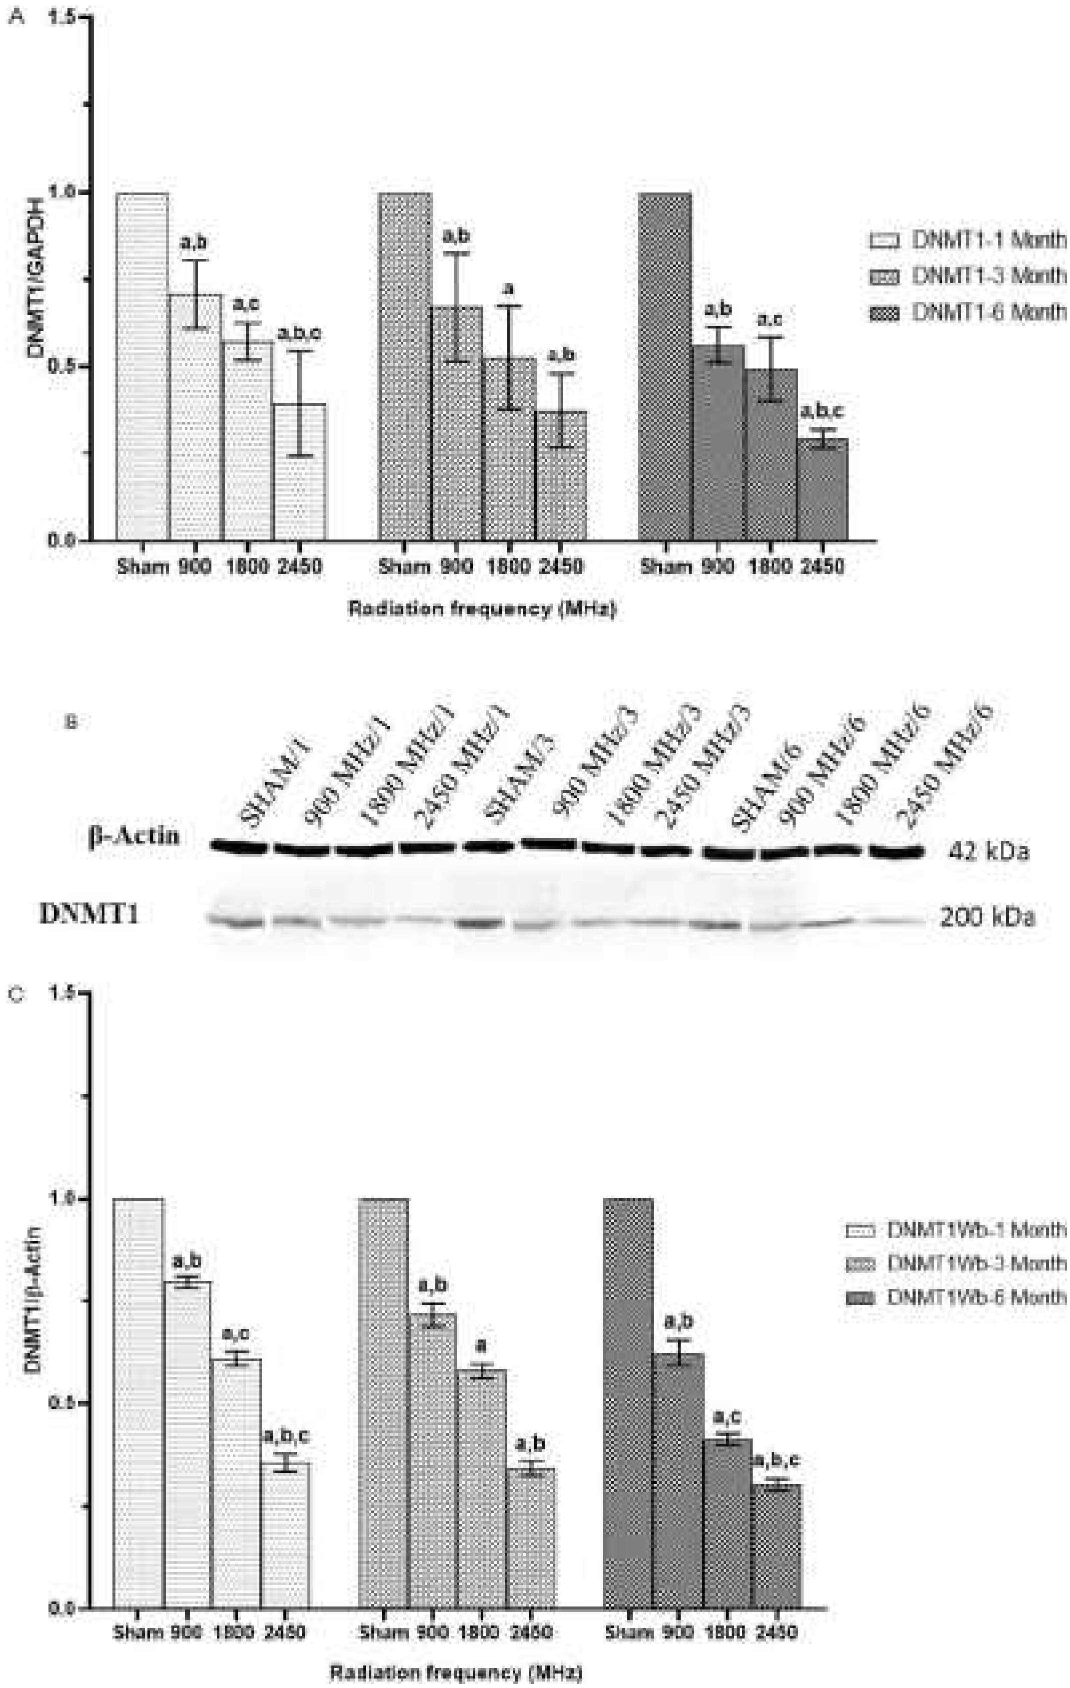

(caption on next page)

Fig. 2. (A) Effect of microwave exposure on *Dnmt1* gene expression in rat brain. The relative transcription levels of DNA methylatransferase1 (DNMT1) in the hippocampus of Wistar rat in response to radiofrequency microwave exposure for one-month, three-month and six-month. Total RNA was extracted from the hippocampus of sham-exposed and microwave exposed Wistar rats and was analyzed by quantitative real-time PCR to deduce the expression level of *Dnmt1* genes. The expressional value of the hippocampus of the microwave exposed Wistar rat were normalized to those of sham-exposed rat. The relative transcriptional values of the *Dnmt1* gene were calculated by normalizing to the GAPDH expression using $2^{-\Delta\Delta Ct}$ (n = 8) method and we found its increasing as with increasing frequency and exposure duration. (B) Western blot of Dnmt1 in the hippocampus of Wistar rat after one-month, three-month and six-month microwave exposure at 900, 1800 and 2450 MHz frequency. (C) Band intensity of Western blot was quantified by dosimetry, and the protein level was normalized relative to β-actin which was shown in the bar diagram. Each bar represents the mean value with ±SD of experiments in triplicates. Statistical significance value accepted in a two-tailed *t*-test, if $p < 0.05$. The respective p-value, *a,b,c significantly different from respective control (p < 0.05) by one way ANOVA followed by Tukey's test.*

when we compared 900 MHz with 2450 MHz exposure group, however no significant decrease in fold change was noticed when we compared 900 MHz with 1800 MHz and 1800 MHz with 2450 MHz exposure group.

Similarly, in the six-month exposure group, significant ($p < 0.05$) downregulation of *Dnmt1*gene mRNA expression with increasing microwave exposure frequency in the hippocampus of rat brain was observed, 0.56-fold in 900 MHz, 0.49-fold in 1800 MHz and 0.30-fold downregulation in 2450 MHz microwave exposure with respect to sham-exposed group respectively (Fig. 2A). In the six-month exposure group, we noticed more downregulation in gene expression with respect to the three-month exposure group at respective frequency. In the post hoc test, a significant ($p < 0.05$) decrease in fold change was noted when we compared the 900 MHz frequency fold change with 2450 MHz frequency and 1800 MHz frequency fold change with 2450 MHz frequency fold change. However, no significant difference was found when we compared 900 MHz fold change with 1800 MHz fold change.

The expression pattern of the *Dnmt1*gene was validated with the Western blot of DNMT1 (Fig. 2B). In the post hoc test, significant ($p < 0.05$) downregulation was noticed in all groups when compared to the sham-exposed group. Data were normalized with housekeeping protein β-actin and shown in the bar diagram (Fig. 2C).

3.3. Histone (H3K9) methylation

Percentage methylation of histones was estimated after one-month, three-month and six-month of microwave exposure as shown in Fig. 3. After one month of microwave exposure, the percentage of methylated H3K9 was observed to be increasing with increasing frequency. Methylated H3K9 in the sham-exposed group was 4.15%, whereas it was 4.90% in 900 MHz, 6.43% in 1800 MHz and 7.40% in the 2450 MHz exposed group. In the post hoc test, a Significant ($p < 0.05$) increase in methylated H3K9 was observed in the post hoc test when we compared the sham-exposed group with 1800 MHz and 2450 MHz exposed group, but not with 900 MHz exposed group. A significant increase in methylated H3K9 was also noticed when we compared 900 MHz exposure group with 1800 MHz and 2450 MHz exposure groups. However, no significant increase was observed when compared 1800 MHz exposure group with a 2450 MHz exposure group.

Methylated H3K9 histone protein was 5.29% in the sham-exposed group, 7.70% in 900 MHz, 8.79% in 1800 MHz and 9.38% in the 2450 MHz following three-month MW exposure. Increased methylation percentage was also noticed with respect to one-month exposure at respective frequency. In the post hoc test, a significant ($p < 0.05$) increase in methylated H3K9 histone protein was observed when we compared sham with 900 MHz, 1800 MHz, and 2450 MHz. A significant increase was also noticed when compared to 900 MHz with 2450 MHz but not between 900 MHz and 1800 MHz. However, no significant difference was observed when we compared the 1800 MHz exposure group with the 2450 MHz exposure group.

An increase in methylated H3K9 histone protein was obtained in the hippocampus of microwave exposed Wistar rat brain as 5.69% in sham-exposed group, 8.67% in 900 MHz, 9.58% in 1800 MHz and 10.38% in 2450 MHz following six-month exposure. Increased methylation percentage was again noticed with respect to three-month exposure at respective frequency. Significant ($p < 0.05$) increase in methylated H3K9 histone protein was observed, when we compared the sham-exposed group with 900 MHz, 1800 MHz, and 2450 MHz exposure group. But when we compared 900 MHz with 1800 MHz and 2450 MHz and 1800 MHz with 2450 MHz, no significant difference was obtained.

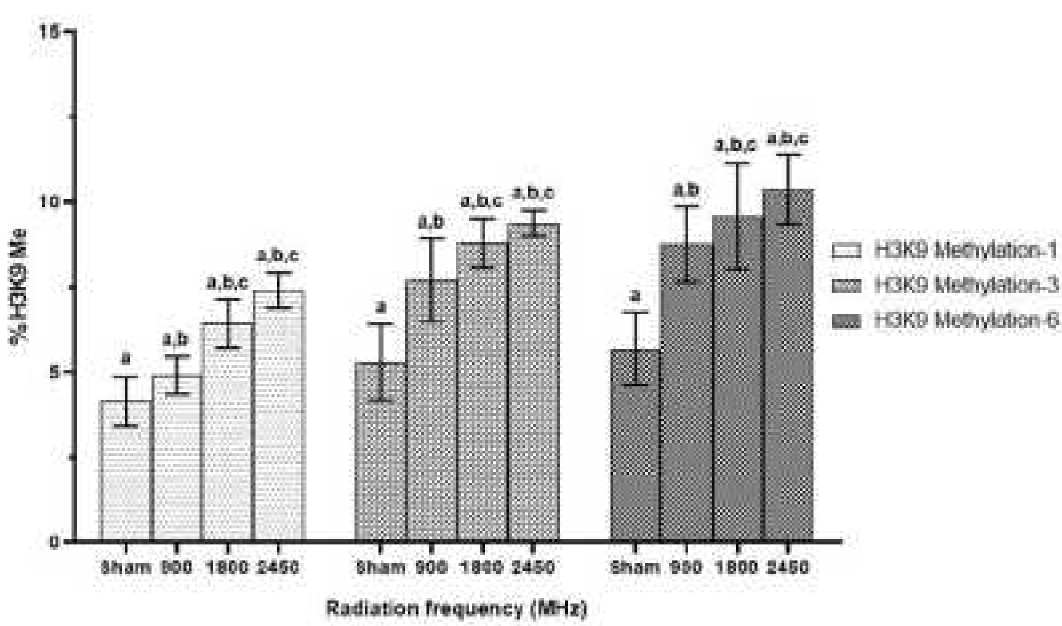

Fig. 3. Percentage Histone methylation (H3K9) in rat brain. *Values are expressed as mean ± SD (8 animals* per *group). The respective p-value, a,b,c significantly different from respective control (p < 0.05) by one way ANOVA followed by Tukey's test.*

3.4. 5-mC DNA methylation

Methylation of cytosine residue of DNA is well associated with the regulation of gene expression. Percentage methylation of DNA was evaluated as shown in Fig. 4. After one-month of exposure, the percentage methylation of 5-mC DNA was decreased with increasing frequency that is 17.23%, 16.81%, 15.04% and 12.96% in the sham-exposed group, 900 MHz groups, 1800 MHz group, and the 2450 MHz exposure group respectively. Significant ($p < 0.05$) decrease in methylation percentage was observed when the sham-exposed group was compared with 2450 MHz, but not when compared with 900 MHz and 1800 MHz. A significant decrease in methylation was observed, when we compared 900 MHz with the 2450 MHz exposure group but not with the 1800 MHz exposure group.

In three-month exposure group, a reduced percentage of methylated DNA was noticed with increasing microwave exposure frequency, 13.91% in the sham-exposed group, 12.69% in 900 MHz, 12.58% in 1800 MHz and 10.48% in 2450 MHz exposed group. Reduced methylation was also observed when compared with the one-month exposure group at respective frequency. In the post hoc test, a significant ($p < 0.05$) decrease in the percentage of methylated DNA was observed using post hoc test when compared to the sham-exposed group with 2450 MHz exposure group but not with 900 MHz and 1800 MHz exposure group. Further, a significant decrease in methylated DNA was also noticed when we compared 900 MHz with 2450 MHz and 1800 MHz with 2450 MHz exposure group.

In the six-month exposure group, a similar decreasing pattern of methylated DNA was noticed with increasing microwave exposure frequency. The sham-exposed group has 12.21% methylated DNA, whereas it is 11.27% in 900 MHz, 8.92 in 1800 MHz and 5.35% in the 2450 MHz exposed group in the hippocampus of Wistar rat. Reduced methylation was also observed when compared with the three-month exposure group at respective frequency. In the post hoc test, a significant ($p < 0.05$) decrease in methylated DNA was observed when we compared the sham-exposed group with 1800 MHz and 2450 MHz exposure groups. A significant decrease was also reported when compared to 900 MHz with 2450 MHz as well as 1800 MHz with a 2450 MHz exposure group.

4. Discussion

Mobile phone signal radiofrequency microwave (900, 1800 and 2450 MHz, 2 h per day for one, three and six month) induce epigenetic modulations in the hippocampus with significant increase in histone (H3K9) methylation, significant decrease in DNA methylation and significant fold change in transcriptional as well as translational level of DNA/histone methyltransferase (DNMT1/EHMT1) enzyme.

We are in constant exposure to electromagnetic radiation, notably under the blanket of artificial electromagnetic radiation, especially microwave radiation, emitted from wireless communication system (mobile phones, Wi-Fi/Bluetooth devices), and surveillance technologies (radar, security scanner) (Bandara and Carpenter, 2018). Due to the dramatic increase of wireless communication systems (cellular phones), the concern raised about the possible effects of mobile phone signals on human health (Myers, 2018). Various study group reported about microwave exposure induced alteration in blood, cord blood (Bektas et al., 2018), placenta (Bektas et al., 2020), ear canal hair follicle (Akdag et al., 2018),as well as in testes (Alkis et al., 2019a). Hippocampus is the primary region of the brain which regulates learning, memory, and behavior (Rubin et al., 2014). Studies reported the evidence in human model of neurodevelopmental or behavioral disorder in children (Divan et al., 2008), altered brain metabolism (Volkow et al., 2011), brain electrical activity (Schmid et al., 2012), DNA damage in peripheral blood lymphocytes (Zothansiama et al., 2017), risk of brain tumor (Carlberg and Hardell, 2017), fatigue, depression, and headaches (Yakymenko et al., 2011). However, microwave exposure affects neurodevelopment and behavior in mice (Aldad et al., 2012), oxidative stress, apoptosis of glial cells (Alkis et al., 2019b; Dasdag et al. 2004, 2009), amyloid protein, protein carbonyl (Dasdag et al., 2012), male fertility (Kesari et al., 2018), neuro inflammations (Megha et al., 2015a) cognitive functions, (Deshmukh et al., 2015; Kleinlogel et al., 2008), and micro RNA expression (Dasdag et al. 2015a, 2015b) in rats, but neither study has reported for epigenetic modulations with microwave exposure.

Our prior study reported that mobile phone signal exposure impairs cognitive functions (Deshmukh et al., 2015), heat shock protein modulation (Deshmukh et al., 2012), neurotransmitter alteration (Megha et al., 2015b), oxidative stress (Alkis et al., 2019b; Megha et al., 2012), and ER-stress in rat brain (Kumar et al., 2019), prompted us to speculate

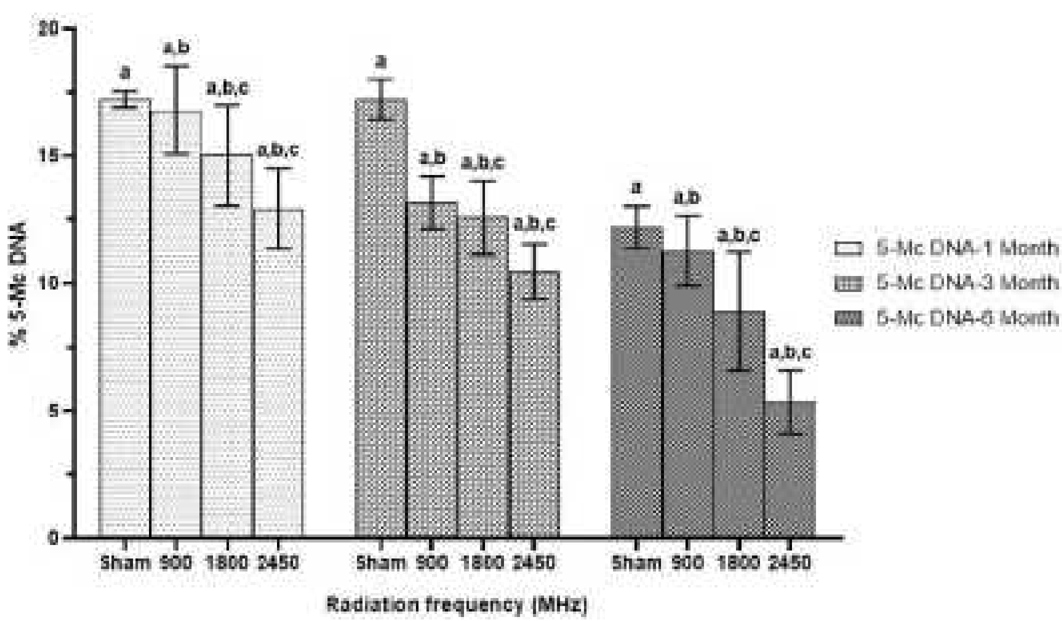

Fig. 4. Percentage methylation of 5-methyl cytosine DNA (5-mC-DNA) in rat brain. *Values are expressed as mean ± SD (8 animals* per *group).* Respective p-value *a,b,c significantly different from respective control ($p < 0.05$) calculated by one way ANOVA followed by Tukey's test.*

that above said changes in neuronal development and behavior crucially driven by epigenetic modulations. We explored our speculation in the present study by evaluating whether mobile phone signal exposure (900–2450 MHz) modulate DNA/histone methylating enzymes and DNA/histone methylation in the hippocampus of Wistar rat. Mobile phone radiofrequency microwave radiation led to significant fold change in euchromatic histone methyltransferase1 EHMT1 (Fig. 1), DNA methyltransferase1 DNMT1 (Fig. 2) enzyme as apparent by hypermethylation of histone, H3K9 (Fig. 3) and hypomethylation of DNA, 5-mC (Fig. 4) at selected mobile phone signal radiofrequency microwave.

We previously reported that radiofrequency microwave exposure of rat to 900–2450 MHz for one to six month exposure induces cognitive impairment. In this study, we extended our observations by elucidating whether radiofrequency microwave exposure induces epigenetic modulations with augmented levels of methyltransferase (DNMT1 and EHMT1) enzymes in the hippocampus compared to sham-exposed rats. Being hippocampus is crucially involved in learning, memory, and behavior, microwave-induced epigenetic modifications of the hippocampus more likely the causative factor.

Hippocampus is the vulnerable and sensitive target of mobile phone signal radiation which may deficits learning and memory (Zhao et al., 2012). However, no data available on the microwave exposure risk to epigenetic modulations. Cognitive functions including long-term/short-term memory are a unique feature of the healthy brain. Differential gene expression changes protein synthesis in memory-related regions of the hippocampus (Bailey et al., 2004). Altered synaptic properties propagate through persisting molecular changes which translate into changes in memory and memory recall processes. Epigenetic modulations (DNA/histone methylation) around gene promoters induce changes in gene expression thus causing cognitive and memory dysfunction (Barroso and Chevet, 2016; Ramos-Lopez et al., 2018). We observed increased H3K9 methylation and euchromatic histone methyltransferase1 enzyme with respect to sham exposed rat, similar observation is reported by Iacono et al., who showed increased H3K9 methylation associated with cognitive dysfunction in mice (Iacono et al., 2018). The ability of learning and memory depends on the transient translation of gene expression which influences synapse activity and connectivity of neurons. Histone methylation under the control of EHMT1 expression, which brings chromatin remodeling (Lagali et al., 2010). EHMT1 enzyme induces histone methylation at lysin residue, which modifies chromatin structure and disturbs gene regulatory networks that affect learning and memory (Koemans et al., 2017). Chromatin is a highly dynamic biomolecule which is readily modulated under the influence of internal or external stimuli. Epigenetic modulations bring reversible covalent modifications of histone or DNA. Epigenetic modulations of histone and DNA modulate DNA–histone interactions and the access of DNA replication and transcription complex, which functions as a transcription gatekeeper that brings cell-specific gene activation or repression (Ng et al., 2009; Parkel et al., 2013). H3K9 methylation is a repressive mark for gene activation (Hathaway et al., 2012) and depressive behavior in animal models as well as in humans (Tsankova et al., 2006). Jarome and Lubin (2013), reported the association of histone methylation in neurodegeneration in mouse brain due to chromatin structure disturbance and blockade of normal gene expression via disruption of transcription regulatory network (Graff et al., 2012; Jarome and Lubin, 2013).

Studies have reported that learning triggers change in DNA methylation in the hippocampus (Lubin et al., 2008). DNA methylation brings transcriptional activation in the adult central nervous system (Chahrour et al., 2008; Suzuki and Bird, 2008). In the present study, we observed decreased DNA methylation and DNMT1 enzyme in microwave exposed rats with respect to sham-exposed rats. We also observed decreasing DNA methylation with increasing frequency (900 MHz–2450 MHz) and with increasing duration of exposure (one-month to six-month exposure group). DNMT1 enzyme is the only maintenance methyltransferase enzyme that maintains and regulates cellular epigenome. It is vital for native chromatin structure as well as embryonic development and neuronal survival (Baets et al., 2015). DNA demethylation hampers the binding of the methyl-CpG binding protein, MeCP2 at the *Zif268* promoter. Binding of MeCP2 with methylated DNA and cyclic adenosine monophosphate response element binding-1 (CERB-1) protein, regulates the transcription of the gene (Chahrour et al., 2008). Lubin et al. reported that the cAMP response element-binding site residing around the *Zif268* DNA promoter region is methylated in adult hippocampal neurons. Learning induces DNA methylation which regulates the transcription of brain-derived neurotrophic factors (BDNF) (Lubin et al., 2011). Repression of DNA methylation via infusion of the DNA methyltransferase1 inhibitor in the hippocampus brings the differential regulation of BDNF variants and reduces the process of learning and memory (Lubin et al., 2008). DNA repair process also mediates active DNA demethylation in the adult hippocampus which involves enzymes removing the methyl group from 5-methylcytosine or removing the whole nucleotide (Kangaspeska et al., 2008; Ooi and Bestor, 2008). Growth arrest and DNA-damage inducible gene 45 alpha (GADD42A), a key regulator of DNA demethylation are also crucially involved in DNA repair, maintenance of genomic stability and cell cycle checkpoints. Several study reports support that DNA demethylation is actively dependent on daily activity and DNA demethylation imparts another level of complexity in the epigenetics of neurobiology (Lubin, 2011). Hence, it also opens a new window with a potential mechanism for the manipulation of DNA demethylation specifically in the restoration of cognitive functions where DNA methylation profile is altered.

Epigenetic modifications play a crucial role in the regulation of cognitive and learning-dependent synaptic plasticity (Gupta et al., 2010; Jiang et al., 2008; Lubin et al., 2011). However, epigenetic modulations are not the only mechanism but also influences several other mechanisms through chromatin structure regulation and transcription and translation machinery via ER-stress and unfolded protein response. DNA methylation in concert with histone methylation redirects the microenvironment of gene promoters and influences transcription of the genes in the hippocampus of the rat brain (Barrett and Wood, 2008; Graff and Mansuy, 2008).

5. Conclusion

In summary, 900–2450 MHz for 2 h daily for one-month, three-month and six-month exposure led to hypermethylation of histone (H3K9) protein by upregulating euchromatic histone methyltransferase1 enzyme, whereas hypomethylation of DNA (5-Mc) by down-regulating DNA methyltransferase1 enzyme with increasing microwave frequency as well as exposure duration of Wistar rat. Band 3 (1800 MHz) is widely used frequency band for communication. Higher frequency corresponds to higher energy, hence more adverse effect than 900 MHz frequency but lower than 2450 MHz, which we also observed in this study in the form of epigenetic modulations, gene expression as well as in protein expression in experimental Wistar rats. We found maximum bio-molecular alteration in six-month exposure group at 2450 MHz frequency, as it possesses maximum energy. Higher frequency and longer duration of exposure responsible for the larger changes in bio-molecular characteristics. Hence 2450 MHz frequency for six month of exposure is the most effective frequency and duration to impart health hazards. The result may deliver insight into the pathway of cognitive impairment induced by mobile phone signal radiofrequency, which may be useful for assessment of mobile phone radiation risk in mental health and setting guidelines for policy makers.

The International Commission on Non-Ionizing Radiation Protection: Conflicts of interest, corporate interests and the push for 5G

Brussels June 2020

This report was commissioned, coordinated and published by two Members of the European Parliament – Michèle Rivasi (Europe Écologie) and Klaus Buchner (Ökologisch-Demokratische Partei), and financed by the Greens/EfA group in the European Parliament.

The report was written by Hans van Scharen with editing and additional research support from Tomas Vanheste. Final Editing: Erik Lambert

Foreword by Klaus Buchner and Michèle Rivasi

This report deals with an issue of which the importance cannot be overrated: the possible health effects of Radiofrequency Radiation (RfR) or electro magnetic fields (EMF); It deals more specifically with how the scientific debate has been hijacked by corporate interests from the Telecom industry.

After having read the reports of a journalistic collective called Investigate Europe, the many articles from Microwave News as well as all the publications from independent scientists from around the world, who for years have all been ringing alarm bells on adverse health effects from the use of mobile phones and EMF, we decided that we needed to dig deeper into this strange, unknown to the public but powerful scientific NGO based in Germany called the 'International Commission on Non-Ionizing Radiation Protection' (ICNIRP).

The findings of this report ('The International Commission on Non-Ionizing Radiation Protection: Conflicts of interest and the push for 5G') give us an uncomfortable déjà-vu: many facts and processes that lead to the actual situation whereby European authorities – from the European Commission to most of the member states – simply close their eyes for real scientific facts and early warnings. We have seen exactly the same scenario in the debate on Tobacco, asbestos, climate change and pesticides.

Also in it's latest guidelines from March this year, ICNIRP assures the world that there is no scientific evidence of adverse health effects from the radiation that comes with the new communication technologies, within the limits it proposes. But at the same time a growing number of scientists and also citizens are worried that EMFs do cause health problems. ICNIRP pretends to be scientifically neutral, and free from vested interests of the Telecom industry. We show with this study that this is 'playing with the truth' or simply a lie.

Already in 2011 Dr. Jacqueline McGlade, Executive Director of the European Environment Agency said on mobile phones and the potential head cancer risk for EMF: "The European Parliament has responded (resolution of April 2009) to this public concern with a resolution on EMF in 2009 which, among other things, called for lowering exposure to electromagnetic fields and for lower exposure limits that would better protect the public from health hazards. We share these recommendations."

McGlade pleaded interim actions to protect public health, particularly for children on the basis of the precautionary principle, as central to public policymaking where there is scientific uncertainty and high health, environmental and economic costs in acting, or not acting, when faced with conflicting evidence of potentially serious harm. "This is precisely the situation that characterises EMF at this point in its history. Waiting for high levels of proof before taking action to prevent well known risks can lead to very high health and economic costs, as we have seen with asbestos, leaded petrol and smoking," said McGlade.

The EEA plea for a precautionary approach to policy making in this area, is based on an evaluation of the existing evidence and on the lessons from earlier hazards, analysed in the EEA "Late Lessons from Early Warnings" project. David Gee, EEA Senior Advisor on Science, Policy and Emerging Issue and on the drivers of this project said: "Mobile phones have numerous social, economic and even environmental benefits", said. "However, there is significant disagreement in the scientific community about whether mobile phone use increases the risk of head cancers. We recommend using the precautionary principle to guide policy decisions in cases like this. This means that although our understanding is incomplete, this should not prevent policy makers from taking preventative action".

In a recent discussion Gee stated that there are “several striking similarities” between 5G/radiofrequency radiation and many of the technologies or substances that featured in the “Late Lessons” case studies. Gee pointed to “a lot of hubristic hype surrounded the introduction of the new technology”. Gee rightfully points to a “marketing hype which is widespread” on 5G and “a failure to systematically and independently scrutinise the claimed benefits and costs of the new technology”. He sees a “gross imbalance between research on developing and promoting the technology and on anticipating and reducing potential harm to people and environments” as well as a “failure to ensure independent research into health and environmental effects that can help combat manufactured doubt”.

Gee was tough for the scientific community because scientists fail to acknowledge what they do not know and ”to properly understand and embrace knowledge from other relevant disciplines”. Gee also sees “a failure of scientists to be transparent about the paradigms, assumptions, judgements and values used in academic science and in their evaluations of scientific evidence in regulatory science. A failure of scientists and policymakers to appreciate complex and variable realities; multi-causality; and the likelihood of inconsistent scientific results. A failure by policymakers to understand the difference between the high strength of evidence needed to establish robust scientific knowledge and the case specific appropriate strength of evidence needed to justify timely preventive action.”

Late lessons from early warnings, is indeed also a clear pattern that rises from this report. And there have been more and more warnings (but unfortunately so far no lessons learned).

Also the Council of Europe adopted in May 2011 a strong resolution on “the potential dangers of electromagnetic fields and their effect on the environment” in which it called upon governments to take all reasonable measures to reduce exposure to electromagnetic fields and said about ICNIRP: “It is most curious, to say the least, that the applicable official threshold values for limiting the health impact of extremely low frequency electromagnetic fields and high frequency waves were drawn up and proposed to international political institutions (WHO, European Commission, governments) by the ICNIRP, an NGO whose origin and structure are none too clear and which is furthermore suspected of having rather close links with the industries whose expansion is shaped by recommendations for maximum threshold values for the different frequencies of electromagnetic fields”.

In an article, ‘Planetary electromagnetic pollution: it is time to assess its impact’, published in *The Lancet (*December 2018) scientists from the Australian research group ORSAA state that out of 2266 studies on EMFs, no less than 68 percent found “significant biological effects or health effects”. Significant biological effects do not necessarily mean that human health will be harmed, but is an important indicator for risk assessment and then for risk evaluation by regulators. To us the atgument that that there is insufficient scientiifc evidence for regulators to act is factual not corect and simply not true.

The International Agency for Research on Cancer (IARC), a global authority on cancer, concluded in 2011 that radiation from mobile phones is a ‘possible’ head cancer risk. And recently an Advisory Group has recommended that IARC should reassess the cancer risks associated with non-ionizing radiofrequency radiation with high priority. According to the panel’s report, published in The Lancet, the group suggests that the new evaluation should take place between 2022 and 2024.

In 2012 a group of 29 independent scientists and health experts from around the world warned in an update of their Bio Initiative 2007 Report, about “possible risks from wireless technologies and electromagnetic fields”. However, they acknowledge that “sometimes, science does not keep pace with new environmental exposures that are by-products of useful things we want to buy and use in society. So, the deployment runs ahead of knowledge of health risks. It is an old story. This is the case for EMF (electric and magnetic fields) and RFR (Radiofrequency radiation)."

The Bio Initiative report underscores the "critical need to face difficult questions, make mid-course corrections, and try to repair the damage already done in this generation, and to think about protecting future generations".

And they state that the existing public safety limits as formulated by the US regulator FCC and by ICNIRP do not sufficiently protect public health against chronic exposure from very low-intensity exposures: "If no mid-course corrections are made to existing and outdated safety limits, such delay will magnify the public health impacts with even more applications of wireless-enabled technologies exposing even greater populations around the world in daily life."

In 2017, more than 200 doctors and scientists from various countries launched the, so-called 5G Appeal, that has since received more endorsements and whose mission statement starts with : "We the undersigned scientists and doctors(…), recommend a moratorium on the roll-out of the fifth generation, 5G, for telecommunication until potential hazards for human health and the environment have been fully investigated by scientists independent from industry."

Since then there have been five replies on this Appeal by the European Commission, the last one dating from December 2019. The first reply, the Commission states that 'the Commission is not aware of any conflicts of interests of members of international bodies such as ICNIRP or the members of SCENIHR'. One of the leading figures of the appeal professor Lennart Hardell stated that this «does not represent the scientific evidence of inherent conflicts of interest both in ICNIRP and SCENIHR. The European Commission seems to be ill-informed or even misinformed, as the EU seems to take information mainly from these two fraudulent organisations, but not from independent researchers. The EU does not seem to rely on sound science and thereby downplays the RF-related risks."

It is clear from this report that ICNIRP itself does not have a sharp definition of conflicts of interest (CoI's), nor does it have a well-developed policy to avoid these kinds of conflicts. It is a crying shame that under the pretext of 'scientific uncertainty' ICNIRP, but especially the European Commission and member states keep on failing to protect their citizens.

We very much agree with the title and content of the latest publication on Microwave News, which reads " The Lies Must Stop, Disband ICNIRP - Facts Matter, Now More Than Ever" . There are two major casualties in this polarised debate: the truth and public health. Both are too important not to protect with all that we have. That is what we consider as our responsibility as elected politicians .

By MEP's Michèle Rivasi (Europe Écologie) and Dr. Klaus Buchner (Ökologisch-Demokratische Partei)

Introduction & Scope

In the last few decades, since the introduction, and rapid expansion, of new communication technologies, there has been a proliferation of electromagnetic fields worldwide. A lot of countries are now about to roll out 5G networks. The International Commission on Non-Ionizing Radiation Protection (ICNIRP) assures the world that this can be done safely and that there is no scientific evidence of adverse health effects within the limits it proposes. But at the same time a growing number of scientists and also citizens are worried that EMFs do cause health problems.

It is therefore high time to look into the workings of ICNIRP. If the European Commission and national governments keep relying on this commission, as is currently the case, we must be completely sure that it functions wholly independently and that there is no evidence of its members being in situations of conflicts of interest.

ICNIRP is a non-governmental organisation (NGO) or association, registered in Munich, specialising in non-ionizing radiation protection. One of the organisation's tasks is to determine exposure limits for electromagnetic fields used by devices such as cellular phones. On its website, ICNIRP states that it is a non-profit organisation with a scientific mission, and that it is "formally recognised as an official collaborating non-state actor by the World Health Organisation (WHO) and the International Labour Organisation (ILO). ICNIRP is consulted by the European Commission and is linked to many organisations engaged in non-ionizing radiation (NIR) protection worldwide through diverse collaborative projects".

ICNIRP states that its "aim is to protect people and the environment against adverse effects of NIR." To this end, it "develops and disseminates science-based advice on limiting exposure to non-ionizing radiation." ICNIRP works with experts from all over the world, from a wide variety of disciplines, including biology, epidemiology, medicine, physics, and chemistry. ICNIRP's also states that its protection advice is based on current scientific knowledge about the biological effects, and the action mechanisms, of radiation for the whole NIR frequency range.

To a large extent, the European Commission, as well as the WHO, depend on the "exposure guidance" and safety advice given by ICNIRP. Furthermore, many EU member states look to the EC and WHO for (European) advice on this issue. Therefore, it goes without saying that ICNIRP has a significant role to play in ensuring the general public is protected against any possible health risks related to electromagnetic fields (EMF).

In March 2019, in a comprehensive report, *How much is Safe?,* *by Investigate Europe*, a collective of investigative journalists from all over Europe, ICNIRP is described as follows:

''ICNIRP is a particularly influential group, as it not only evaluates radiation and health risk research, but also provides guidelines for radiation safety limits that most countries use. It is a private, German-registered organisation located outside Munich, behind a yellow door on the premises of the German Federal office for radiation protection. Decisions on who to invite in, are taken by ICNIRP itself."

The report highlighted the close links that exist between ICNIRP and other important organisations in the field of health protection.

Most European governments and radiation protection authorities rely mainly on these four scientific bodies for advice on non-ionizing radiation protection:

- The international commission on non-ionizing radiation protection, ICNIRP.
- The EU Scientific Committee on Health, Environment and Emerging Risk, SCENIHR / SCHEER.
- The World Health Organisation WHO's International EMF Project.
- The WHO Cancer Unit IARC, International Agency for Research on Cancer.

Investigate Europe showed the close links between especially the first three bodies. "The groups, however, are to a remarkable degree, staffed by the same experts," it stated. "Of 13 ICNIRP scientists, six are members of at least one other committee. In the WHO group, this applies for six out of seven (members)." The SCENIHR Working Group on EMF also counts two ICNIRP-members.

In view of the rapid expansion of EMF's, in particular in the context of the planned deployment of 5G networks in which telecom and media operators have huge financial and economic vested interests, and given the evidence of closed circles of experts involved in determining health guidelines in this field, critical scrutiny on the functioning of ICNIRP is important and necessary.

New guidelines

In March 2020, ICNIRP published its latest 'Guidelines on Limiting Exposure to Electromagnetic Fields', designed for "the protection of humans exposed to radiofrequency electromagnetic fields (RF) in the range 100 kHz to 300 GHz. The guidelines cover many applications such as 5G technologies, Wi-Fi, Bluetooth, mobile phones, and base stations."

This publication replaces and supersedes earlier publications from 1998 and 2010. In a press release from March 11th 2020, the then ICNIRP Chairman, Dr Eric van Rongen (now co-chair) said: "The new electromagnetic field guidelines have taken seven years to develop and are more appropriate than the 1998 guidelines for the higher frequencies that will be used for 5G in the future. We know parts of the community are concerned about the safety of 5G and we hope the updated guidelines will help put people at ease. When we revised the guidelines, we looked at the adequacy of the ones we published in 1998. We found that the previous ones were conservative in most cases, and they would still provide adequate protection for current technologies."

Van Rongen's main message was that when the new ICNIRP guidelines are followed 5G is absolutely safe. He stated: "The new guidelines provide better and more detailed exposure guidance, in particular for the higher frequency range, above 6 GHz, which is of importance to 5G, and future technologies using these higher frequencies. The most important thing for people to remember is that 5G technologies will not be able to cause harm when these new guidelines are adhered to."

So, this is how ICNIRP presents itself: an independent organisation that gives sound scientific advice on safety guidelines with respect to non-ionizing radiation and that ensures citizens remain safe.

However, this description raises doubts on two levels: Firstly, is ICNIRP really independent and also, are its assurances that non-ionizing radiation is absolutely safe when their guidelines are applied correct? Our report will focus on the question of ICNIRP's independence, but first, we will briefly outline the current debate around the safety guidelines.

The health debate

The possible adverse health effects of non-ionizing radiation, mainly microwave radiation form mobile phones and other wireless devices/infrastructure, is a highly sensitive and polarising issue. In some countries citizens and scientists plead for the application of the 'pre-cautionary principle' in relation to the rolling out of 5G networks, whilst associations such as ICNIRP maintain that "the most important thing for people to remember is that 5G technologies will not be able to cause harm when these new guidelines are adhered to."

In 2012 a group of 29 independent scientists and health experts from around the world published an update of their Bio Initiative 2007 Report, about "possible risks from wireless technologies and electromagnetic fields". The scientists, of which ten holding a medical degree, still update their "rationale for Biologically-based Public Exposure Standards for Electromagnetic Fields (Extremely low frequency, ELF and radiofrequency, RF)" by assessing the latest scientific research and reporting on it. However, they acknowledge that "sometimes, science does not keep pace with new environmental exposures that are by-products of useful things we want to buy and use in society. So, the deployment runs ahead of knowledge of health risks. It is an old story. This is the case for EMF (electric and magnetic fields) and RFR (Radiofrequency radiation)."

The Bio Initiative report underscores the "critical need to face difficult questions, make mid-course corrections, and try to repair the damage already done in this generation, and to think about protecting future generations".

And they state that the existing public safety limits as formulated by the US regulator FCC and by ICNIRP do not sufficiently protect public health against chronic exposure from very low-intensity exposures: "If no mid-course corrections are made to existing and outdated safety limits, such delay will magnify the public health impacts with even more applications of wireless-enabled technologies exposing even greater populations around the world in daily life."

In an article, 'Planetary electromagnetic pollution: it is time to assess its impact', published in *The Lancet Planetary Health* in December 2018, scientists (from the Oceania Radiofrequency Scientific Advisory Association, ORSAA, and the Institute for Health and the Environment, of the University at Albany) state that out of 2266 studies on EMFs, no less than 68 percent found "significant biological effects or health effects". Significant biological effects do not necessarily mean that human health will be harmed, but is an important indicator for risk assessment and then for risk evaluation by regulators.

The authors stated that it is high time for a wide-ranging debate on the rapid global proliferation of artificial electromagnetic fields. “The most notable is the blanket of radiofrequency electromagnetic radiation, largely microwave radiation generated for wireless communication and surveillance technologies, as mounting scientific evidence suggests that prolonged exposure to radiofrequency electromagnetic radiation has serious biological and health effects.”

Unfortunately, this mounting evidence did not result in policy changes, the authors from ORSAA observe. “However, public exposure regulations in most countries continue to be based on the guidelines of the *International Commission on Non-Ionizing Radiation Protection* and Institute of Electrical and Electronics Engineers, which were established in the 1990s on the belief that only acute thermal effects are hazardous. Prevention of tissue heating by radiofrequency electromagnetic radiation is now proven to be ineffective in preventing biochemical and physiological interference”.

“For example, acute non-thermal exposure has been shown by NIH scientists, to alter human brain metabolism, electrical activity in the brain and systemic immune responses. Chronic exposure has been associated with increased oxidative stress and DNA damage, and cancer risk. Laboratory studies, including large rodent studies by the US National Toxicology Program and Ramazzini Institute of Italy, confirm these biological and health effects in vivo. As we address the threats to human health from the changing environmental conditions due to human activity, the increasing exposure to artificial electromagnetic radiation needs to be included in this discussion.”

The results of the National Toxicology Programme (NTP) the mentioned Lancet-authors referred to, were presented at the end of 2018. The U.S. Food and Drug Administration (FDA) nominated radio frequency radiation (RFR) used by cell phones for an NTP study because of the widespread public use of cell phones and the limited knowledge about potential health effects from long-term exposure. The study found that high exposure to RFR (900 MHz) used by cell phones was associated with:

- Clear evidence of tumours in the hearts of male rats. The tumours were malignant schwannomas.
- Some evidence of tumours in the brains of male rats. The tumours were malignant gliomas.
- Some evidence of tumours in the adrenal glands of male rats. The tumours were benign, malignant, or complex combined pheochromocytoma.

However, ICNIRP criticised the NTP-study, saying that it did not prove a link between Radio Frequency, Electro Magnetic Fields and carcinogenesis. But according to scientists like Lennart Hardell, an oncologist, professor and researcher at the University hospital in Örebro in Sweden, the ICNIRP rebuttal of the NTP-study was unfounded. The NTP-study leading scientist Ronald Melnick recently also published a comment on the ICNIRP-note in which he criticizes ICNIRP’s ”incorrect statements” and “false claims”.

James Lin, professor at the University of Illinois in Chicago and also editor of the online journal, *Bioelectromagnetics*, published a remarkable and nuanced review of the NTP-study in late 2019. The review is remarkable because, from 2004 to 2016, James Lin was himself a member of ICNIRP. As stated above, ICNIRP basically dismisses the NTP-study. However, basing his conclusions partly on the NTP-study, Lin now questions if the existing safety guidelines are still adequate: “An outstanding question persists on the adequacy of these guidelines for safe long-term exposure to RF radiation at or below 1.6 or 2.0 W/kg. Perhaps, the time has come to judiciously reassess, revise, and update these guidelines.”

Lin’s review is nuanced in so much as he uses the peer-review process to analyse the conception and all possible methodological ‘problems’ of the NTP-study in depth: “This project is the largest NTP animal cancer study ever. It was nominated by the Food and Drug Administration (FDA) in 1999. The supposedly 5-year project was sole sourced in 2004 to an industrial research firm as the project’s principal investigator. The work began in 2005. However, the project had been protracted for more than a dozen years with huge budget overruns, and an estimated eventual price tag of $25 million.”

Somewhat surprisingly, at the end of his review, Lin advocates for wireless radiation to “get a more stringent cancer risk class": “Now that the NTP review panel has concluded that there is clear evidence of carcinogenicity from long-term RF exposure in rats, is it conceivable that IARC would upgrade its epidemiology-based classification of RF exposure to the next higher levels of carcinogenicity to humans?” Lin seems to suggest that IARC should put cell phone radiation in WHO-hazard class 1 (carcinogenic), instead of today’s 2B (possibly carcinogenic).

Worldwide, there is rapidly growing concern and a proliferation of publications about EMF, specifically concerning the out-roll of new generation 5G. On this subject, we will only cite a 2019 in-depth report called “5G Deployment: State of Play in Europe, USA, and Asia”[1]. It reads: “Increased exposure may result, not only from the use of much higher frequencies in 5G, but also from the potential for the aggregation of different signals, their dynamic nature, and the complex interference effects that may result, especially in dense urban areas. (…) The 5G radio emission fields are quite different to those of previous generations because of their complex beam-formed transmissions in both directions – from base station to handset and for the return.”

The authors state that with 5G we are entering unknown territory. “Although fields are highly focused by beams, they vary rapidly with time and movement and so are unpredictable, as the signal levels and patterns interact as a closed loop system. This has yet to be mapped reliably for real situations, outside the laboratory. (..) The problem is that currently it is not possible to accurately simulate or measure 5G emissions in the real world.”

The debate on the safety of non-ionizing radiation is fascinating, heated and important, and has been on-going for at least 30 years. This paper however does *not* go further into the scientific debate on the possible levels of harm to public health caused by non-ionizing radiation, mainly from mobile phones. We will focus on the independence of ICNIRP and the possible existence of conflicts of interest of its members.

[1] A study requested by the ITRE committee of the European Parliament, published in 2019 by the Policy Department for Economic, Scientific and Quality of Life Policies - Directorate-General for Internal Policies.

The importance of funding

ICNIRP claims it is “free of vested interests”. ICNIRP's funding relies on grants from public bodies. Additionally, ICNIRP members and ICNIRP SEG members may not be employed by industry.

But not being “employed by industry” is not, in itself, sufficient to avoid conflicts of interest. It is also important to ascertain to what extent ICNIRP research activities may be funded by industry.

It is a well-established fact that the source of funding for scientific research can have an influence on the outcomes of research. A clear and precise explanation of how this is may occur can be found on the website of UC Berkeley:

“In a perfect world, money wouldn't matter — all scientific studies (regardless of funding source) would be completely objective. But of course, in the real world, funding may introduce biases — for example, when the backer has a stake in the study's outcome. A pharmaceutical company paying for a study of a new depression medication, for example, might influence the study's design or interpretation in ways that subtly favour the drug that they'd like to market. There is evidence that some biases like this do occur. Drug research sponsored by the pharmaceutical industry is more likely to end up favouring the drug under consideration than studies sponsored by government grants or charitable organisations. Similarly, nutrition research sponsored by the food industry is more likely to end up favouring the food under consideration than independently funded research.”

“This does not lead to the conclusion that we should ignore any research funded by companies or special interest groups”, Berkeley says. But it is a reason for the need “to scrutinize studies funded by industry or special interest groups with extra care. *So, don't, for example, brush off a study of cell phone safety just because it was funded by a cell phone manufacturer — but do ask some careful questions about the research before jumping on the bandwagon*. Are the results consistent with other independently funded studies? Does the study seem fairly designed? What do other scientists have to say about this research? A little scrutiny can go a long way towards identifying bias associated with funding source.”

“A little scrutiny” is perhaps an understatement. In the 2013, the ‘Late lessons from early warnings’ report produced by the European Environment Agency (EEA), a chapter written by Lisa A. Bero, describes the various opinions on how to deal with private funding of scientific research without compromising an independent non-biased outcome and/or publication of that research.

For example, various researchers argue that it is logical for industry to fund research, in so much as it is about their products that concerns exist. Former ICNIRP scientist Norbert Leitgeb, professor at the Institute of Health Care Engineering at the Graz University of Technology in Austria, told *Investigate Europe* that what is crucial is the putting in place of effective firewalls to ensure that “private partners cannot interfere with researchers and influence scientific outcomes or conclusions”.

That the source of funding has an important influence, is also something various ICNIRP-researchers acknowledge. For example, in 2009 two scientists who are now members of the ICNIRP-commission – Anke Huss and Martin Röösli – where co-authors of a systematic review that showed that “industry-sponsored studies were least likely to report results suggesting effects”. They concluded that the correlation between the “source of funding and conflicts of interest are important in this field of research.”

in his evaluation of the NTP-study, another former ICNIRP-member, professor James Lin, also pointed to the dominance of the telecom industry in the research: “The FDA should be applauded for nominating, and NIEHS/NTP should be lauded for having sponsored the research and conducted the Cell Phone Radio Frequency Radiation (RFR) Studies. It’s important for the U.S. government to step in to conduct such a research program, and not leave the matter entirely to the cell phone industry. The wireless industry has had nearly free reign to develop and roll out cellular mobile phones and related RF devices as they see fit. (…)”. Lin goes on to quote figures from the ‘systematic review’: “A systematic review of 59 published studies of controlled exposure to RF radiation with health-related outcomes [10] showed that public agencies or charities funded 11 (19%), the wireless communications industry funded 12 (20%), mixed sources (including industry) funded 14 (24%), and in 22 (37%) the source of funding was not reported.”

This specific debate has been ongoing for many years, as *Investigate Europe* reports: “At least three studies over the years have documented that there is often a link between conclusions of studies and the source of the money that paid for the research. Science funded by industry is less likely to find health risks than studies paid for by institutions or authorities.”

In ‘How much is safe?’ by *Investigate Europe*, Lennart Hardell, an oncologist, professor and researcher at the University hospital in Örebro in Sweden, a critical EMF researcher, warns that although funding for research often goes to universities with “firewalls” put in place between the individual scientist and the funder, the problem is, that researchers can come to depend on this private funding to safeguard the future of their research.

Hardell carries out research on the possible links between long-term mobile use and brain cancer and has published results that indicate that there are correlations between the two. Hardell was a member of the IARC committee that researched EMF-effects, but is not a member of (any) other committees concerned with the effects of non-ionizing radiation. *Investigate Europe*: “According to Hardell, his research is funded through his salary from the hospital, as well as by funds raised by local cancer foundations and national organisations. “Of course, I have also worked a lot on my free time”, he says.”

There are some ICNIRP-researchers who acknowledge that it is possible for the source of funding to influence conclusions, but they say that they are very aware of this and cautious to avoid it. For example, Gunnhild Oftedal, - associate professor at the Norwegian University of Science and Technology, who specialises in research on the effects of electromagnetic fields on humans, and is a member of ICNIRP and therefore part of “the small international network that determines what science to trust” said to *Investigate Europe* that “today we are concerned about it. I have the impression that scientists are much more cautious about receiving support from the industry – at least direct support.”

What about the direct funding received by ICNIRP itself? ICNIRP states that its “funding stems from subsidies granted by national and international public institutions such as the German Federal Ministry for the Environment, Nature Conservation, and Nuclear Safety

(BMU), the European Union Programme for Employment and Social Innovation (EaSI) 2014-2020 (EC - Directorate General Social Affairs), and the International Radiation Protection Association (IRPA)."

"Occasionally, ICNIRP also receives support to organise meetings or workshops from national ministries or radiation protection agencies, such as the Australian Radiation Protection and Nuclear Safety Agency (ARPANSA), and the Turkish Ministry of Health (MoH). Funding is reported yearly in the ICNIRP annual reports". ICNIRP also acknowledges that it receives funding from national or international public organisations and via private donations. But ICNIRP claims that in order to safeguard its independence, "only donations from private individuals or from businesses not related in any way to the field of non-ionizing radiations can be accepted. For reasons of transparency, donations cannot be anonymous and are listed in an ICNIRP donors' report."

According to the ICNIRP 2018 annual report, it received € 132,150 in subsidies. The Australian research group ORSAA points out that these kinds of funding sources are not always as neutral as they may seem: "ICNIRP funding partly comes from government regulatory bodies, such as, for example, the Australian Radiation Protection & Nuclear Safety Agency (ARPANSA). What is actually going on is best described as 'money laundering' by the Telecom industry through government (ARPANSA) and onto WHO's International EMF Project and ICNIRP."

In Australia, as is the case for many countries worldwide, the government issues spectrum licences to Telecom operators for large sums of money – often in the billions. In Australia, this licensing is the remit of the industry regulator ACMA, the Australian Media Communications Authority. ORSAA explains that ACMA also collects a separate levy, or tax, from the wireless industry, money that is earmarked for scientific research on RF-EMR health effects: "This has remained a set amount of $1M per annum since 1997, despite the massive increases in wireless industry revenues."

According to ORSAA, ACMA then diverts $300,000 to another government body, ARPANSA (Australian Radiation Protection & Nuclear Safety Agency) for its public information campaign, and $700,000 to the National Health & Medical Research Council (NHMRC). From the $300,000 received annually by ARPANSA, a portion goes to the WHO's IEMFP (some years ago this was around $50,000 a year), and finally, it appears that a portion goes to ICNIRP. So, after a long trajectory, money from the Telecom industry does end up with ICNIRP, which is contrary to the statement on the ICNIRP website: "Only donations from private individuals or from businesses not related in any way to the field of non-ionizing radiations can be accepted."

Still according to ORSAA, "the money that the Australian NHMRC receives in order to provide grants for medical research has mostly gone to industry-friendly researchers who have direct links with the wireless industry. For example, the largest recipient of these NHMRC research funds is Prof. Rodney Croft, a psychology researcher at the University of Wollongong, who held the role of Director of the Australian Centre for Electromagnetic Bio-effects Research (ACEBR) for many years[2]. Rodney Croft has essentially been the head of RF-EMR health research in Australia, despite his questionable qualifications for this health research role.

[2] See also portrqit of Rodney Croft on pqge 50 of this report.

Notably, he has led ICNIRP's RF-EMR exposure guidelines development team and now he has been elected as the next Chairman of ICNIRP as from May 2020. Prof. Croft has received ample direct industry funding in addition to his lucrative NHMRC grants, which should be termed indirect industry funding."

Finally, ICNIRP states on its website that all its experts "are required to comply with the ICNIRP policy of independence and declare their personal interests. (...) These are key elements to ICNIRP's commitment to independence and transparency, which ICNIRP believes is fundamental to carrying out its scientific mission."

Whether those declarations of interests are really checked is something that the Italian 'Vallisoletana Association of people affected by mobile phone antennas' (AVAATE) questioned in their public statement from July 2015, attacking ICNIRP: "It is hard to understand whether ICNIRP investigates the Declarations filed by appointed members of the ICNIRP Commission and Scientific Expert Committee, since in some cases these members report that they work or have worked for these organisations but do not specify what they have done or whether they are paid. It is also hard to understand how ICNIRP controls the content of the declarations by the appointed members of their Expert Committees, when in most cases the most contentious aspects of the biographical statement are not reported in these statements."

The citizens behind AVAATE also ask "how ICNIRP controls the content of the declarations by the appointed members of their Expert Committees when, at least in five cases, the persons concerned have not signed their statements".

Corporate capture

In the debate on EMF and possible health effects, terms like 'corporate capture' of scientific research and 'war game science' are often used, and references to the tactics of the tobacco industry are often made. According to several authors, these tactics also influence organisations like ICNIRP and WHO's International EMF Project.

In the 2013 'Late lessons from early warnings' report produced by the European Environment Agency (EEA), in collaboration with a broad range of external authors and peer reviewers, these tactics are described in detail in the chapter entitled 'Tobacco industry manipulation of research'. The focus is on "the strategies used by the tobacco industry to deny, downplay, distort and dismiss the growing evidence that, like active smoking, ETS causes lung cancer and other effects in non-smokers." Author Lisa A. Bero concentrated "on the 'argumentation' that was used to accept, or reject, the growing scientific evidence of harm. Who generated and financed the science used to refute data on adverse health effects? What were the motivations? What kind of science and information, tools and assumptions were used to refute data on the adverse health of tobacco?"

Bero says: "The release of millions of internal tobacco industry documents due to law suits in the US has given insights into the inner workings of the tobacco industry and revealed their previously hidden involvement in manipulating research. However, this insight is not available for most corporate sectors."

Bero also discusses the possibilities of 'full disclosure' of funding sources and special interests in research and risk assessment in order to secure independence and prevent bias towards particular viewpoints. She states that “while smoking bans are now being introduced in more and more countries, other industries are drawing inspiration from tobacco company strategies, seeking to maintain doubt about harm in order to keep hazardous products in the marketplace.”

With respect to the EMF-debate, according to Bero, public institutions or authorities should adhere to the following: “when data on risk appear to be controversial, users of the data investigate the sources of the controversy. Does the controversy exist only because the findings of interest group-funded research are contrary to data collected by others? Is the controversy supported primarily by evidence published in interest group-supported publications? (…) Policymakers should apply these questions to all situations in which a company has an interest in creating controversy about the risks of its products.”

According to Bero, the tobacco industry's methods for influencing the design, conduct and publication of research are similar to those of other corporate interests.

One of the leading researchers in the US who defends the viewpoint that the same tactics are being used by Telecom companies is Theodora Scarato, Executive Director of the US based [Environmental Health Trust](#) (EHT). As a policy analyst, Scarato manages and updates the comprehensive EHT database on international policy that documents the 20+ nations that have protective policies in place to reduce public exposure to cell phone and wireless radiation.

Scarato and EHT claim that “Just as the Tobacco Industry created a ‘Playbook’ to defend cigarettes and manufacture doubt about the health effects of cigarettes, the Wireless Industry seems [to have a fine-tuned the “Playbook” of advertising, public relations and industry-funded science](#) to defend wireless products and falsely reassure the public that cell phones and wireless products are safe.”

“Key to this public relations effort are industry created resources, websites and materials that communicate the myth of no proof of harm from wireless products. These are all part of the Playbook to manufacture doubt that a problem exists. Examples of such propaganda range from glossy brochures, Questions and Answers on Hot Topics such as “children and cell phones”, websites on EMF and Health and research forums.”

And according to Scarato, “these materials are paid for, designed and prepared by ‘non-profit’ organisations that are created by telecom and wireless companies pooling money together. When citizens raise concerns about a particular product or when research comes out indicating a health risk, companies can simply pull from these materials to respond as if there are no concerns”.

These kind of tactics, used to influence science and risk assessment, also have their repercussions for standard-setting bodies like ICNIRP and WHO’s International EMF Project, according to scientific researcher Don Maisch (in his PhD thesis ‘An examination of the manipulation of telecommunications standards by political, military, and industrial vested interests at the expense of public health protection’): “In an ever increasingly globalised world the reliance on international organisations to set standards to protect public health seems inevitable. Proposed internationalised standards such as ICNIRP’s recommendations act as an aid to economic development by not hindering trade that might conflict with stricter national standards (such as the Russian Federation, the Czech Republic's former standard and China for example). In the delicate trade-off between economic benefits and adequate health protection, international organisations should ideally be "eternally vigilant" to ensure that their tasks are not co-opted by vested interest groups that are the producers of risks to be regulated."

This appears to be a global issue. US researcher, Norm Alster, in his report 'Captured Agency' describes what this kind of corporate capture can lead to by referring to the workings of the FCC (Federal Communications Commission), which is the main official US institution that deals with Telecom issues, and is sometimes mentioned in critiques of ICNIRP: "That is a term that comes up time and time again with the FCC. Captured agencies are essentially controlled by the industries they are supposed to regulate. A detailed look at FCC actions—and non-actions—shows that over the years the FCC has granted the wireless industry pretty much what it has wanted".

"As a result, consumer safety, health, and privacy, along with consumer wallets, have all been overlooked, sacrificed, or raided due to unchecked industry influence. (…) Most insidious of all, the wireless industry has been allowed to grow unchecked and virtually unregulated, with fundamental questions on public health impact routinely ignored. (…) Industry control, in the case of wireless health issues, extends beyond Congress and regulators to basic scientific research. And in an obvious echo of the hardball tactics of the tobacco industry, the wireless industry has backed up its economic and political power by stonewalling on public relations and bullying potential threats into submission with its huge standing army of lawyers. (…) Industry behaviour also includes self-serving public relations and hyper aggressive legal action. It can also involve undermining the credibility of, and cutting off funding for, researchers who do not endorse cellular safety. It is these hardball tactics that recall 20th century Big Tobacco tactics."

Conflicts of Interest

In 2017, almost 200 doctors and scientists from various countries launched the, so-called 5G Appeal, that has since received more endorsements and whose mission statement starts with : *"We the undersigned scientists and doctors(…), recommend a moratorium on the roll-out of the fifth generation, 5G, for telecommunication until potential hazards for human health and the environment have been fully investigated by scientists independent from industry."*
Since then, as professor Hardell describes in his article "Appeals that matter or not on a moratorium on the deployment of the fifth generation, 5G, for microwave radiation" published in January 2020, there have been five replies on this Appeal by the European Commission, the last one dating from December 2019. The first reply, by the Commission (from October 13, 2017 by the Directorate-General Health and Food Safety) states that *'the Commission is not aware of any conflicts of interests of members of international bodies such as ICNIRP or the members of SCENIHR'*.

However, according to Hardell, "that does not represent the scientific evidence of inherent conflicts of interest both in ICNIRP and SCENIHR. The European Commission seems to be ill-informed or even misinformed, as the EU seems to take information mainly from these two fraudulent organisations, but not from independent researchers. The EU does not seem to rely on sound science and thereby downplays the RF-related risks."

Given the important effects of funding on research outcomes described above, there can be no doubt that it is extremely important for ICNIRP to ensure it avoids any possibility of conflicts of interests in the way that it, or any of its members, function. In its statutes, it writes: 'No member of the Commission shall hold a position of employment that, in the opinion of the Commission, will compromise its scientific independence.'

The crucial words here are '*in the opinion of the Commission'*. The Commission evaluates itself about possible conflicts of interest. There are no clear rules by which the Commission judges if any of its members interests compromise its scientific independence. In its statement on the declarations of interests ICNIRP writes:

"The evaluation of personal integrity is very complex and might never be achievable in a perfect way. It is the duty of the ICNIRP Commission to carefully consider and decide if the declared interests potentially constitute a conflict of interest."

It is clear from this that ICNIRP itself does not have a sharp definition of conflicts of interest (CoI's), nor does it have a well-developed policy to avoid these kinds of conflicts.

It is useful to refer to a recent study requested by the European Parliament's Petitions (PETI) committee which, as a key message, said that "EU institutions and agencies lack a consistent definition of conflicts of interest and common rules on transparency'. This same study also stated that "a coherent policy should be developed for the required length of time between working in the industry and being called to a committee among agencies with a similar function, i.e. risk assessment".

In the online newsletter, *Politico*, the Greek MEP Alexis Georgoulis said: "There is a legal inconsistency between the definitions of the conflicts of interest that should clearly cover any conflicts between public and private functions, but also public functions with other public functions," The report recommends clear clarifications on whether conflicts of interest are potential or also perceived.

So, we will have to look at other, similar, organisations that have more stringent policies in this field. The European Food and Safety Authority (EFSA) seems to be a good candidate. In June 2017, EFSA, after a long history of accusations of CoI's, sharpened its definition and its policy to avoid CoI's.

EFSA defines a conflict of interest as "any situation where an individual has an interest that may compromise or be reasonably perceived to compromise his or her capacity to act independently and in the public interest in relation to the subject of the work performed at EFSA".

This definition is also somewhat broad and vague. EFSA's solution was to set clear rules to which its experts have to comply. For example: Research funding from the private sector benefiting EFSA's experts should not exceed 25% of the total research budget.

The EFSA-rules are minimum requirements. According to *Corporate Europe Observatory* they are not strict enough to completely avoid conflicts of interest. So, it is reasonable to say that

ICNIRP, that presents itself as an independent, scientific advisory board, should, at the very least, comply with the EFSA rules.

In this paper, we will therefore:

* Give an overview of the history and all existing knowledge on the independence of, and the conflicts of interest within, ICNIRP. These chapters provide the context in which we have a closer look at the ICNIRP-members.

* Try to identify all the potential sources of conflicts of interest of ICNIRP-members. Such as: research funding from the private sector; financial investments in, and employment by, telecom business operators; consultancy work for the telecom industry.

* Try to find out if the ICNIRP-members comply to the EFSA-rules on conflicts of interest and give an assessment on the independence of ICNIRP.

These are the ICNIRP experts whose professional backgrounds we will research (see the portraits of each member in Part V):

As from December 2019, the composition of the ICNIRP Commission for the term of office 2020-2024 is as below. The new term of office starts in May 2020.

MEMBERS OF THE ICNIRP COMMISSION:

GUNDE ZIEGELBERGER (SCIENTIFIC SECRETARY), GERMANY
RODNEY CROFT (CHAIR), AUSTRALIA
ERIC VAN RONGEN (VICE-CHAIR) , THE NETHERLANDS

TANIA CESTARI, BRAZIL
NIGEL CRIDLAND, UNITED KINGDOM
GUGLIELMO D'INZEO, ITALY
AKIMASA HIRATA, JAPAN
ANKE HUSS, NETHERLANDS
KEN KARIPIDIS, AUSTRALIA
CARMELA MARINO, ITALY
SHARON MILLER, USA
GUNNHILD OFTEDAL, NORWAY
TSUTOMU OKUNO, JAPAN
MARTIN RÖÖSLI, SWITZERLAND
SOICHI WATANABE, JAPAN

MEMBERS WHO HAVE LEFT THE ICNIRP COMMISSION IN MAY 2020
Maria Feychting
Adèle Green
Zenon Sienkiewicz

MEMBERS OF THE SCIENTIFIC EXPERT GROUP (SEG):
JACQUES ABRAMOWICZ - PG COSMETICS, PG ULTRASOUND
ANSSI AUVINEN - PG DATA GAPS
CHRISTIAN CAJOCHEN - PG SHORT WAVE LIGHT
JOSE GOMEZ-TAMES - PG HF DOSIMETRY REVIEW

I- Historic overview of ICNIRP and accusations of COI

In this chapter, we give an overview of the history of ICNIRP as an organisation and examples of accusations of Conflicts of Interests (COI) and other controversies concerning the organisation's work. The authors do not want to suggest that this overview is, by any means, complete or comprehensive.

About ICNIRP's history, on its website, the organisation simply states that its beginnings go back to 1973 "when, during the 3rd International Congress of the International Radiation Protection Association (IRPA), for the first time, a session on non-ionizing radiation protection was organized. In 1977 the International Non-Ionizing Radiation Committee (INIRC) was created. This Committee was the immediate forerunner of ICNIRP that was chartered as an independent Commission in 1992 during the IRPA 7th International Congress."

In a speech in Rio de Janeiro, in 2008, Paolo Vecchia, the Italian former ICNIRP-chair (2004-2012), explained in more detail: "In June 1974, IRPA President, Italian Carlo Polvani (1973-1977), proposed "a possible role of IRPA in establishing criteria and standards in the field of health protection against non-ionizing radiations" and the IRPA Executive Council decided to set up a Working Group to review the health protection problems arising from different non-ionizing radiation (NIR)."

One could argue that IRPA itself, and then much later it's spin-off ICNIRP, came into existence as a "fall-out" of the first US atomic bomb testing. On its website, on the subject of its historical background, IRPA states: "Before the Second World War, radiation protection had been a largely secondary concern of radiologists and radiological physicists. With the concentration of effort under the Manhattan Project it was soon realised that this would involve working with quantities and types of radiation and radioactive materials that had not previously been envisaged. As a result, a distinct group of scientists within the project were assigned full time to what was termed "Health Physics"."

In an article from 2017 on the history of of ICNIRP, at the occasion of it's 25th anniversary founder Mike Repacholi wrote: "Concern about health risks from exposure to non-ionizing radiation (NIR) commenced in the 1950s after tracking radars were first introduced during the Second World War. Soon after, research on possible biological effects of microwave radiation in the former Soviet Union and the U.S. led to public and worker exposure limits being much lower in Eastern European than in Western countries, mainly because of different protection philosophies." As we will see further in this chapter this divide between Russia and the West on safety measures on non-ionizing radiation exists till today.

At the end of its conference in 1955, the US Atomic Energy Commission voted overwhelmingly to form a professional Health Physics Society and the first IRPA Congress was held in Rome between 5-10 September 1966. It is interesting to see that many of the 12 Executive Council Members of IRPA in 1966 remained in position for many years; a fact that echoes like a prelude to criticism that ICNIRP functions like an 'old-boys network'.

In 1974, IRPA President Polvani insisted that "a separate and independent International Commission on NIR Protection (later ICNIRP) should be established…The ICNIRP would look to IRPA as the sponsoring international scientific organization in a similar way that ICRP looks to the International Congress of Radiology…. And "IRPA should consider broadening its institutional authority to include NIR".

So Carlo Polvani got what he wanted: the General Assembly amended the Constitution of IRPA so that it could "also apply its objectives and purposes in the field of non-ionizing radiation protection". Then the General Assembly created an International NIR Committee […] "with the objective of developing background documents and internationally accepted recommendations". This became INIRC, set up in 1977, that went on to become ICNIRP, in 1992. Already four years earlier, Mike Repacholi (more on him later), a member of IRPA, had begun writing the charter for ICNIRP which was signed in 1992.

But why elaborate so much on IRPA, before turning to ICNIRP itself? Critics often ask from where ICNIRP got its self-acclaimed international and institutional authority? Well, partly from IRPA, which still plays a role in the actual composition of ICNIRP. The IRPA Charter for the creation of ICNIRP, from 1992, says: "The election of the members of the Commission shall be made by the Commission from current members of the Commission and from nominations submitted by the Commission itself, the Executive Council of IRPA and the IRPA Associate Societies, with regard to an appropriate balance of expertise. Attention shall be paid to geographical representation."

At the end of the 15th International Congress of IRPA, planned for 11-15 May 2020, in Seoul, Korea, the new term of office of the new ICNIRP commission (2020-2024) would officially start. This occurred, despite the international congress in South-Korea being postponed until 2021 due to the corona-crisis. This international congress counts telecom companies of all kinds among its sponsors (platinum, silver, bronze as well as others). Since ICNIRP was born from IRPA, and that, like any parent, IRPA still exerts a strong influence over ICNIRP, and considering ICNIRP claims to function free of any vested interests, it seems important to us to look more closely at IRPA.

And maybe also because of the actual role that IRPA wants to play in the ongoing debate around safety and health in relation to EMF. Current IRPA-president, Roger Coates, writes that "a lot of effort over recent times has gone into preparing the IRPA Guidance for Engagement with the Public on Radiation and Risk". This seems to be the typical type of response given by bodies like IRPA, ICNIRP and others concerning public worries about possible health effects: *let's explain things better, because the public doesn't understand (…that everything is safe)*. It is the same kind of response given in the past by the nuclear sector when people started to become worried about nuclear safety issues (for example after Chernobyl).

Some governments – at various levels – try to put into practice a guiding principle of radiation safety, called "ALARA", which stands for "As Low As Reasonably Achievable". This principle means that even when being subjected to a small dose, if receiving that dose has no direct, practical or medical benefit, you should try to avoid it. IRPA-boss Roger Coates states that "the interpretation of what is 'Reasonable' in the implementation of optimisation of radiation protection is one of the key issues for our profession and is one of IRPA's current key themes. It is central to practical protection and is the dominant factor controlling exposures in any well-developed system of protection. But what does 'reasonable' mean?

There are growing concerns within our profession that we are giving more emphasis to 'as low as' and 'minimisation' rather than truly being 'reasonable'."

On the subject of safety: before Roger Coates became IRPA-president he had a life-long career in the British nuclear industry: he started working in 1975 at the Health Physics and Safety Department at the Sellafield site of *British Nuclear Fuels plc (*BNFL) and did so for over 30 years, "holding radiation protection roles covering operations, environmental protection and emergency planning. His responsibilities broadened to encompass nuclear safety, together with conventional safety and environmental issues. He completed his industry career as Director of Environment, Health and Safety for both BNFL and its British Nuclear Group subsidiary." Over the years, BNFL has had to face up to quite some issues in the field of safety and was the subject of a "damning report into the falsification of safety data at the Sellafield reprocessing plant" at the start of this century.

This year, on its website, IRPA published the first new safety guidelines of ICNIRP since 1998, of which ICNIRP-chair Van Rongen said, as we mentioned earlier: " The new guidelines provide better and more detailed exposure guidance in particular for the higher frequency range, above 6 GHz, which is of importance to 5G and future technologies using these higher frequencies. The most important thing for people to remember is that 5G technologies will not be able to cause harm when these new guidelines are adhered to."

Self-declared legitimacy

Since the signing of IRPA-charter in 1992, ICNIRP is based in Munich, Germany and registered as a self-governed NGO (non-governmental organisation) that was formally recognized as "an official collaborating non-state actor by the World Health Organization (WHO) and the International Labour Organization (ILO)." ICNIRP is consulted by the European Commission and is linked to many organizations engaged in NIR protection worldwide through diverse collaborative projects.

As mentioned in the introduction of this report, extensive reporting by *Investigate Europe*, in March 2019 (updated on June 10th 2020), showed that there are many close links between ICNIRP and other leading organisations in the field of health protection. Many ICNIRP-members are, or were, also members of one of these three scientific bodies (from which most radiation safety authorities in Europe and governments, seek their advice) and it is important to mention them again, because these are the bodies that guide government policies in most countries:

- The EU Scientific Committee on Health, Environment and Emerging Risk, SCENIHR / SCHEER.
- The World Health Organization (WHO) International EMF Project (IEMFP).
- The WHO Cancer Unit IARC, International Agency for Research on Cancer.

It is worth underlining, however, that IARC does not really fit into this "gang of four" because it has a much more critical and independent approach. IARC published a report in May 2011 which concluded that radiofrequency (RF) radiation is "possibly carcinogenic" to humans.

The IARC cancer classification includes all sources of RF radiation, of which the long-term exposure can come from mobile phone base stations, Wi-Fi access points, smart phones, laptops and tablets.

However, IARC may now have a solid reputation as independent scientific body, some years ago, IARC also got into trouble. Anders Ahlbom, senior professor of Epidemiology at the Karolinska Institute in Stockholm, and a long standing, influential member of ICNIRP (Commission Member and ICNIRP SCI working group (Epidemiology)), and ICNIRP Chairman from 1996 until 2008, was also part of the IARC panel of experts in 2011. Ahlbom was, until very recently, doing assessments of environmental health risks as chair of the Swedish Radiation Safety Authority's (SSM), the scientific council on electromagnetic fields, as a member of ICNIRP and of the EU advisory body SCENHIR.

But he was asked to step down from IARC after a journalist exposed him as being on the board of his brother's consulting firm in Brussels, which helps clients on telecoms issues. He had not made IARC aware of this. As the Swedish investigative reporter, Mona Nielsson, wrote: "Furthermore, Anders Ahlbom's brother, Gunnar Ahlbom, was for a long time a lobbyist for Swedish telecom giant Telia (previously TeliaSonera) in Brussels. At the same time Anders Ahlbom served as an "independent expert" on several important expert panels, in Sweden as well as at the WHO and EU. At a meeting organized by the European Commission in cooperation with GSM Association and Mobile Manufacturers Forum in Brussels in 2004, Anders Ahlbom was an invited expert to speak on health effects, while his brother Gunnar Ahlbom sat in the audience representing TeliaSonera."

There was, and is, more controversy and division on this topic within the WHO. In a 2017 article, "A hard nut to crack", professor Lennart Hardell draws attention to a Fact Sheet issued by WHO in June 2011, only two months after the IARC's report adapting the cancer classification of RF radiation, which stated that "to date, no adverse health effects have been established as being caused by mobile phone use". According to Hardell, this statement was "not based on scientific evidence at that time on a carcinogenic effect from RF radiation. And it was certainly a remarkable conclusion by WHO since IARC is a part of WHO, although seemingly independent". And he goes on to conclude: "Considering the WHO statement of 'no adverse health effects' the aim might have been to undermine the IARC decision and give the telecom industry a 'clean bill' of health."

One of the main reasons for this schizophrenic approach within the WHO is to be found in the figure of ICNIRP-founder, Mike Repacholi, and the WHO's International EMF Project, IEMFP) (see more below). At least four ICNIRP-members were, or are, also members of the WHO-EMF Group.

In January 2019, in the German newspaper Der Tagesspiegel, investigative journalists described ICNIRP as "a Cartel", that systematically refutes all studies that show possible harm: "And no radiation protection agency, no EU commissioner and no minister, contradicts this. For European governments and their authorities, the 13 members of the self-appointed Commission act as a kind of force majeure. But why? Why are all the warners, even prominent figures like the panel of experts for the US Health and Safety Executive, not heard?"

The Investigative journalists describe an “astonishing phenomenon: the members of ICNIRP are simultaneously active in all the relevant institutions and thus have control over the official discourse.” They then go on to note that, legally speaking, ICNIRP is an association that auto-controls itself and thus avoids dissenting opinions, but in the first instance, the connection with the German state begins with the chosen address of ICNIRP which is the same as the German Federal Office for Radiation Protection (BfS).

Is it just a strange coincidence that ICNIRP’s secretariat is located in the building of the BfS in Munich. The scientific coordination for/of/within? ICNIRP has, for the last few years, been the responsibility of a BfS official: Gunde Ziegelberger. “Her predecessor even chaired the club until 2016. At the same time, the German government supports the NGO of scientists with about 100,000 euro a year. The spokesperson rejects the impression that the private organization is almost part of the German authority as "not applicable". The office only supports the international network of research, she said. Moreover, the ICNIRP is officially recognised by the WHO, which gives it legitimacy.”

We have asked Mrs Ziegelberger via email if she would agree to answer our questions on ICNIRP in writing, but we have, to this date, received no response (the ten questions can be found in Annex I)

This self-declared sense of legitimacy was carefully created by the Australian scientist, Michael Repacholi, who co-founded ICNIRP and also, a few years later, in 1996, the EMF Project of the WHO (officially the WHO’s International EMF Project, IEMFP) of which he became the head. The WHO’s International EMF Project (IEMFP) basically based itself on ICNIRP’s guidelines and by doing so gave itself a “quality label”.

ICNIRP under Michael Repacholi’s chairmanship

Since 1978, the Australian biophysicist, Repacholi, has been a member of the International Non-Ionizing Radiation Committee (INIRC), a part of the International Radiation Protection Association (IRPA), and between 1988—1992 he was chairman of INIRC, which then became into ICNIRP. Between 1996 and 2006, Repacholi called the shots at the WHO by creating, and then leading, the WHO EMF Project, to study the health effects of electric- and magnetic-field radiation (EMF).

So, almost simultaneously with his leadership of ICNIRP, Repacholi was able to set up the EMF Project of the WHO (officially the WHO’s International EMF Project, IEMFP) in 1996, and became its head (see more below) until 2006. From the very beginning, the WHO EMF Project and ICNIRP have been intertwined, as Louis Slesin wrote in *Microwave News*. Given the central role of Repacholi, it might explain why, from very early on, ICNIRP was officially recognized by the WHO. From 1996 until today, Repacholi has been “Member Emeritus” of ICNIRP and today, still has access to the organisation he founded.

As early as 1992, ICNIRP adopted Repacholi’s 1984 IRPA proposal that the only health issue to address in standard setting was the short-term effects due to the absorption of RF/MW energy of sufficient power to be converted to heat, based on the IEEE’s (Institute for Electrical and Electronic Engineers) Radiofrequency standard philosophy. Since then it seems to be carved in stone that ICNIRP only recognises the ‘thermal effects’ of radiation as a serious concern. This is a crucial element to understand the position of ICNIRP, it was built on the logics and thinking of electrical and electronic engineers and completely lacking biomedical expertise.

In 1998, ICNIRP published its first “Guidelines on limits of exposure to time-varying electric, magnetic and electromagnetic fields (up to 300 GHz)”, still largely produced under the chairmanship of Repacholi.

A fierce and long-standing critic of the first ICNIRP guidelines was Dr Neil Cherry, Associate Professor of Environmental Health. In November 1999, Dr Cherry was invited by the Ministry of Health/Ministry for the Environment of New Zealand to carry out a peer-review of the proposal to adopt the ICNIRP guidelines for cell sites in New Zealand.

Cherry: “The ICNIRP guidelines were covered by a published assessment in 1998. This review shows that the assessment had ignored all published studies showing chromosome damage. It was highly selective, biased and very dismissive of the genotoxic evidence and the epidemiological evidence of cancer effects and reproductive effects. The assessment gives the strong impression of being predetermined in the belief that the only effects were from high exposures that cause electric shocks and acute exposures that cause tissue heating. For, example, they cite two studies saying that they do not show any significant increased effects of Brain/CNS cancer from microwave exposures when the actual published papers, Grayson (1996) and Beall et al. (1996), both do show significant increases of Brain/CNS cancer.”

In September 2000, he presented evidence of Health Effects of Electromagnetic Radiation to the Australian Senate Inquiry into Electromagnetic Radiation. The Inquiry Chairperson, Senator Lyn Allison, described Cherry’s evidence as the only independent professional evidence with no relation to industry. The conclusions from this evidence are strongly contrasted with the position of Dr Michael Repacholi, the WHO, ICNIRP, the Australian Radiation Laboratory and many other organisations around the world.

Twenty years ago, Cherry said: “This issue has been so politicized. There are two major casualties, the truth and public health. On these matters, I have no respect for the position of ICNIRP, nor that of the WHO. The WHO position is taken solely by Dr Repacholi. ICNIRP is a small self-appointed, self-promoted group that claims standing by having WHO recognition. In other words, a body formed in part and led by Dr Repacholi, claims its standing by being recognized by Dr Repacholi.”

Cherry used harsh words for INCIRP under Repacholi's chairmanship. “They consistently misquote and misrepresent the published research results. They reject all epidemiological evidence because every single epidemiological study occurs with mean exposure levels and orders of magnitude below their thermally-based standard. They are highly selective, using only a small proportion of the available studies in order to construct and defend their own case. They prefer author's conclusions that there are no effects, even when the data and analysis in the paper clash with this and contradict it. They dismiss large, reliable and well-defined studies as ill-defined and unreliable. They state that studies don't show significant increases in CNS cancers when they actually do, even when the papers include significant dose-response relationships. Both the WHO and ICNIRP, under Dr Repacholi's leadership, have maintained the thermal view to the present, despite the large and ever-growing body of scientific research that firmly and conclusively challenges this.”

He also accused Repacholi of maintaining close links with industry. "He not only appeared in New Zealand in two court cases for industrial clients, in Vienna he was taken to an industry sponsored press conference where he stated that there was no evidence that GSM cell phones were hazardous to health. At the conference, he presented his paper on the Telstra (**Telstra** is Australia's largest mobile network operator and telecom company) funded project that showed that GSM cell phone radiation at quite low non-thermal levels, doubled the cancer in mice. When challenged by the conference chairman, Dr Michael Kundi, Dr Repacholi said that a study is not evidence until it is replicated. The conference rejected this. A study is evidence. Replication provides confirmation and establishment."

The fact is that Repacholi has followed a remarkable career path, from member of IRPA and working in an Australian hospital, to holding a dominant position in the international debate on EMF risks. He also developed as a scientist, from publishing a study in 1997 on lymphoma incidence in mice exposed to RF radiation, to becoming a consultant for telecom and power companies ten years later.

In 2017, he published 'A History of the International Commission on Non-Ionizing Radiation Protection (ICNIRP)' in the scientific review *Health Physics*, in which he stated: "ICNIRP's guidelines have been incorporated into legislation or adopted as standards in many countries. While ICNIRP has been subjected to criticism and close scrutiny by the public, media, and activists, it has continued to issue well-received, independent, science-based protection advice. This paper summarizes events leading to the formation of ICNIRP, its key activities up to 2017, ICNIRP's 25th anniversary year, and its future challenges."

It is quite revealing that Repacholi writes, "ICNIRP has been subjected to criticism and close scrutiny by the public, media, and activists", and yet, forgets to mention, *and also by scientists*. Because, since the first publication of guidelines by ICNIRP in 1998, there has been a never-ending stream of critical academics publishing harsh analysis on the scientific work of ICNIRP. The issue is that Repacholi has not only been a dominant figure, but also a very divisive figure, in the international EMF-debate and he has been able to make sure that independent scientists who do not agree with the ICNIRP-dogma of 'thermal effects only" have not become part of ICNIRP nor of the WHO EMF Project.

The fact that, in his article for the 25th anniversary of ICNIRP, Repacholi makes no mention of the criticism and close scrutiny by scientists is quite telling. Because basically, the story of ICNIRP and the ongoing controversy and ever deeper divisions within the scientific community in the EMF-debate, started around the persona of Michael Repacholi himself.

'Good science' and the EMF Project (IEMFP)

As we have stated above, Repacholi was not only ICNIRP chairman, but also the leader of the WHO EMF Project. In his own words: "The WHO established the International EMF Project to provide a mechanism for resolving the many and complex issues related to possible health effects of EMF exposure. The Project assesses health and environmental effects of exposure to static and time varying electric and magnetic fields in the frequency range 0 - 300 GHz, with a view to the development of international guidelines on exposure limits."

In 1999, Repacholi published the Proceedings of an International Seminar on EMF Risk Perception and Communication that took place in Canada. The event was not only sponsored by the WHO, some government ministries and the Faculty of Medicine at the University of Ottawa, but also by the Cellular Telephone Industry Association, the Canadian Wireless Telecommunications Association and some electricity companies. The almost 300-page document published by Repacholi's "International EMF Project" (part of the WHO's Department of Protection of the Human Environment) kicks off with this statement: "Possible health effects of exposure to electromagnetic fields (EMF) have led to concerns among the general public and workers that appear to go well beyond those that are attributed to well-established risks. It is necessary to understand why this occurs and to deal with it through an effective communications programme. People have the right to access reliable, credible and accurate information about any health risks from EMF exposure."

In his review, "A hard nut to crack", professor Hardell writes: "Michael Repacholi immediately set up a close collaboration between WHO and ICNIRP (being head of both organizations) inviting the electric, telecom and military industries to meetings. He also arranged for large part of the WHO EMF project to be financed by the telecommunication industry's lobbying organisations; GSM Association and Mobile Manufacturers Forum, now called Mobile & Wireless Forum (MWF)." Hardell states that Repacholi acted like "a representative for the telecom industry while responsible for the EMF health effects department at the WHO"

An investigative article in US magazine, *The Nation*, stated: "Although Repacholi claimed on disclosure forms that he was "independent" of corporate influence, in fact Motorola had funded his research: While Repacholi was director of the WHO's EMF program, Motorola paid $50,000 a year to his former employer, the Royal Adelaide Hospital, which then transferred the money to the WHO program. When journalists exposed the payments, Repacholi denied that there was anything untoward about them because Motorola had not paid him personally."

According to *The Nation*, "eventually, Motorola's payments were bundled with other industry contributions and funnelled through the Mobile and Wireless Forum, a trade association that gave the WHO's program $150,000 annually. In 1999, Repacholi helped engineer a WHO statement that "EMF exposures below the limits recommended in international guidelines do not appear to have any known consequence on health."

In a *Microwave News* article, Repacholi claims that he always followed the WHO rules on funding and that, "NO funds were EVER sent to me." But the article's author, Louis Slesin goes on to say that "this is financial *legerdemain*. As *Microwave News* has previously reported, Repacholi arranged for the industry money to be sent to the Royal Adelaide Hospital in Australia, where he used to work. The funds were then transferred to the WHO. Seven years ago, Norm Sandler, a Motorola spokesman, told us that, "This is the process for all the supporters of the WHO program." At the time, Motorola was sending Repacholi $50,000 each year. That money is now bundled with other industry contributions and sent to Australia by the Mobile Manufacturers Forum (MMF), which gives the project $150,000 a year."

A scientist who is very critical about the activities of Repacholi is American Professor Andrew A. Marino (who used to work at the departments of Orthopedic Surgery, Neurology, and

Cellular Biology & Anatomy at the LSU Medical School in Louisiana) wrote: "In 1996 the World Health Organization began what it said was a program to assess the scientific evidence of possible health effects of EMFs. But the project was corrupted from the start because it was controlled by the power- and cell-phone companies in the industrialized countries. The companies designated Michael Repacholi as the project head. He had long been a consultant and spokesman for power companies, so it was unrealistic to expect him to conduct an open and honest inquiry, but his performance in office was even more miserable than could have been anticipated based on his known conflict-of-interest."

Marino: "While heading the EMF program at WHO, Repacholi dealt almost exclusively with experts on the payroll of cell-phone and power companies. Scientists who disagreed with the viewpoint of the EMF companies were excluded from the EMF evaluation process. The public was also excluded from participation even though it was a major stakeholder in the EMF debate. Only pro-industry spokesmen were heard in Repacholi's star-chamber processes, which ultimately resulted in reports and evaluations that exonerated the companies from any responsibility for human disease produced by their EMFs."

Marino saw Repacholi at the Annual Meeting of the Bioelectromagnetics Society (BEMS) in Cancun, Mexico, in June, 2006: "The Mobile Manufacturers Forum, a consortium of the world's major cell-phone companies, were "Gold Sponsors" of the BEMS meeting, and the leaders of BEMS, had invited Repacholi to give a talk entitled "Results from 10 Years of WHO's International EMF Project," which he delivered at a plenary session of the meeting. Unsurprisingly, his talk was a paean to his EMF activities at WHO. He was proud of having successfully stemmed the tide of concern regarding the link between environmental EMFs and other human diseases, and of having defended the principle that man-made environmental EMFs were harmless. He touted model legislation that he had drafted, and said that he hoped it would be enacted by various governments so that the fact that environmental fields were safe would be enshrined in law."

In 2006 Repacholi stepped down as director of WHO's EMF Project.

Not much later *Microwave News* announced: "It's Official: Mike Repacholi Is an Industry Consultant And He's Already in Hot Water": "Just months after leaving his post as the head of the EMF project at the World Health Organization (WHO), Mike Repacholi is now in business as an industry consultant. The Connecticut Light and Power Co. (CL&P), a subsidiary of Northeast Utilities, and the United Illuminating Co. (UI) have hired Repacholi to help steer the Connecticut Siting Council away from a strict EMF exposure standard."

To strengthen his testimony on behalf of the two electric utilities, Repacholi cited the findings of an unfinished WHO report —Environmental Health Criteria (EHC)— on EMF risks. Twenty invited experts drafted this report at a meeting in Geneva in October 2019. The final version was expected to be made public months ago but it's still being edited by the WHO staff.

According to Chris Portier, who chaired the expert EHC panel for the WHO, Repacholi has misrepresented the group's conclusions: "The paraphrasing sometimes has gone a bit far and may be misleading". Portier is the associate director for risk assessment at the National Institute of Environmental Health Sciences (NIEHS)." (see below).

Portier cites a couple of examples. For example, in a summary of the WHO report, Repacholi states that the EHC panel concluded that "The epidemiological evidence cannot be used as a basis for standards (exposure limits)”. Portier retorts, “Such a statement is absurd, since they obviously can be used."

Repacholi has since also been involved in an industry propaganda video and interviews with GSM Association and Hydro Quebec where he clearly speaks in favour of the telecommunications and the power industries, respectively.

A year later, in 2007, *Microwave News* reported that “Mike Repacholi has now revealed that up to half of the funds raised for his EMF Project came from industry. This admission was made in an interview with *Resource Strategies Inc*. in an effort, he states, to “set the record straight.” While Repacholi has acknowledged in the past that he raised funds from industry, the extent of the industry support is much greater than anyone has previously suspected. Repacholi has never disclosed how much money he received nor from whom. He insists that the EMF Project was not “influenced by industry.”

According to an e-mail seen by *Microwave News*, Repacholi touts the interview as an example of “where the press finally got it right”: “*Resource Strategies*, however, can hardly be considered "the press" in the usual meaning of the term. *Resource Strategies* is a corporate consulting firm that prepares briefing papers for clients, which are almost exclusively in the wireless and electric utility businesses. Among them are *EPRI, FGF, GSM Association* and *MMF*. All of these industry groups supported the EMF Project during Repacholi’s tenure. And to bring it all full circle, the WHO is also on *Resource Strategies*’ client list.”

Some current ICNIRP members, such as the new chair, Rodney Croft, also declare doing work for EPRI.

Researcher Don Maisch wrote that Repacholi harmed the credibility of the WHO: “It is acknowledged that in an ever increasingly globalized world the reliance on international organisations to set standards to protect public health is an irrefutable fact of modern life. It is also a fact that international organizations charged with this task need to be “eternally vigilant” to ensure that their organisations are not co-opted by vested interest groups – as exampled by Big Tobacco and WHO. However, when it comes to non-ionizing radiation issues (in this case for power frequency health risk assessment) the evidence is clear that Michael Repacholi has used his standing in both WHO and ICNIRP to stack the WHO’s Environmental Health Criteria Task Group for power frequency exposures with representatives of the power industry in contravention of WHO policy.”

Maybe one of the most telling episodes in the professional life of Repacholi is his open fight with his former boss, Gro Harlem Brundtland, who was director-general of the WHO. In interviews and a speech, Brundtland admitted that she is ‘electrically sensitive’: “I never place a mobile phone next to my head because in one second I would develop a bad headache.” Repacholi was not amused. In 2012, several Norwegian newspapers reported that the “Former head of WHO’s EMF project and ICNIRP chairman says that Brundtland has created “fear of mobiles” in the population”. He offered to examine her, as if she had a psychological problem.

Very seldom were critical voices heard within the WHO. From the minutes of the Sixth International Advisory Committee meeting in May 2001, we read that Russian professor Yuori Grigoriev (the one from the ‘angry letter’ mentioned below) tabled a document outlining EMF activities in Russia, and the difficulties with standards harmonization “particularly because of the inadequate consideration of non-thermal effects by ICNIRP and other national authorities”.

Dr Paolo Vecchia, of the National Institute of Health in Italy, and later ICNIRP chair, reacted to this by saying that “it is important to be able to recognize what good science is. WHO should be a reference point or clearinghouse for good science and good scientific review. It is important to recognize that science and legal measures follow the technology – it is not possible to do a mobile phone epidemiological study before the introduction of the technology! Given the pace of new technological development it is not possible, even now, to envisage the complete set of new research that will be needed.”

Vecchia also claimed to be personally very concerned about ‘defensive science’, speaking of over-cautiousness and an over-emphasis on uncertainties. “Scientists should be more confident ‘about the state of art’”. He is now doing consultancy work and speaks at Telecom-conferences.

IEEE/ ICES

In 2008, Vecchia wrote: “Guidelines for safe exposure to electromagnetic fields have also been developed by other international organizations, in particular the Institute of Electrical and Electronics Engineers (IEEE). Apart from some differences in terminology and numerical values of the limits, these guidelines are based on the same methodological approach, the same structure, and the same scientific database as ICNIRP.”

In his thesis on “an examination of the manipulation of telecommunications standards by political, military, and industrial vested interests at the expense of public health protection” ORSAA-member and scientist, Don Maisch, compares the ICNIRP and IEMFP with the American based IEEE. It is interesting because while ICNIRP claims to be free from the influence of private interests, IEEE/ICES has always openly had members of the military and of the telecom industry among its ranks.

Maisch writes: “On the part of both IEMFP and ICNIRP, a disregard for their own stated principles on independence from industry and following questionable criteria for evaluating science, suggests an agenda to cut off the scientific controversy over EMF human health hazards by less than scientific means. It could be argued that IEEE’s openly industry and military dominated standard-setting process is at least more honest than WHO / ICNIRP masquerading as independent scientific voices free of vested interest machinations.”

Dariusz Leszczynski, Adjunct Professor at the University of Helsinki, writes about conflicts of interest concerning ICES: “ICES, equivalent of ICNIRP, prepares safety recommendations for the exposures of users by radiation emitted by cell phones. Unlike ICNIRP, anyone can apply for membership of ICES and all members of ICES participate in the decision-making process. Sounds nice… Not a “private club” as ICNIRP where participation is by invitation only and the invitees have to have the same opinion on radiation safety – this helps in reaching unanimous decisions… But ICES has another problem that caused me, member of ICES for a couple of years, to resign my membership in 2009. The problem is that the ICES membership is clearly dominated by scientists working or consulting for telecoms."

And in another blogpost Leszczynski wrote: "The membership of the IEEE-ICES-TC95 consists predominantly of the industrial scientists and the committee is chaired by C.K. Chou since the time he was employed by Motorola. This means that all safety standards being developed by IEEE-ICES-TC95 are, in practice, developed by the industry scientists for the use by the industry they are employed by. The industry scientists have the majority on the committee and upper-hand in any process involving democratic voting. To me this is clear Conflict of Interests".

In the portraits of ICNIRP chair, Croft, and co-chair, Van Rongen, we describe (from page 50) how they worked on establishing closer relations between ICNIRP and ICES.

From the minutes of a meeting by the IEEE/ICES TC95 working groups at a Motorola headquarters, a few interesting things got clear: In 2017 Repacholi was still a member of the "ICES literature systematic review working group". And ICES-chair Faraone Antonio from 'Motorola Solutions' proudly announced that "ICNIRP has delayed finalizing their conclusions to give full consideration of ICES's recommendations".

Former Motorola employee Chou stated at the same meeting on the interaction with World Health Organization (WHO EMF Project) that "in response to C-K Chou, the WHO has agreed to encourage international harmonization of RF Safety Limits, especially between ICNIRP and ICES"

And concerning the WHO EMF Project, Hardell describes how Repacholi recruited Emilie Van Deventer to the WHO EMF Project in 2000, and to this day, she remains project manager at WHO for the EMF project: "She has been a long time member of the industry dominated organization Institute of Electrical and Electronics Engineers (IEEE). IEEE has prioritized international lobbying efforts for decades especially aimed at the WHO." Hardell states that Van Deventer is an electrical engineer and has no formal or earlier knowledge in medicine, epidemiology or biology, so it is surprising that she was selected for such an important position at the WHO. Hardell: "The very same year she was recruited to the WHO EMF Project, Toronto University Magazine wrote about Emilie van Deventer's work, stating that it was 'invaluable' to industry: 'The software modelling done by teams like van Deventer's is invaluable.' 'The industrial community is very interested in our research capabilities,' says Van Deventer. 'It always needs to be working on the next generation of products, so it turns to universities to get the research done'."

The importance of this work is reflected in the research funding van Deventer and her team received from the Natural Sciences & Engineering Research Council of Canada (NSERC), Communications & Information Technology Ontario (CITO), and their major industrial partner, Nortel. "We are fulfilling a very real need in the industry today, which will only increase as technology creates more opportunity. In the process, consumers will continue to enjoy faster computers, lighter cell phones, smaller electronic organizers and the vast array of other electronic gadgets the high-tech world has to offer."

In 2016, during a seminar at the SSI, concerning health effects of EMF, former Swedish investigative journalist, Mona Nilsson, asked both Emilie van Deventer, Head of the WHO

EMF Project, and Eric van Rongen, the then chair of the ICNIRP, "whom the citizens should believe: them or the opinion of 220 scientists who signed an Appeal submitted to the United Nations and the WHO?". Both Van Rongen and Van Deventer answered the question without defending their position. Apparently, neither Van Rongen or van Deventer are willing to fully defend the reliability of the evaluation of science by ICNIRP, because as Leszczynski points out, neither of them said that ICNIRP evaluation of science is reliable and that the Appeal's conclusions are unreliable. "This clearly demonstrates that there is no scientific consensus on the health effects of radiation emitted by wireless communication devices. This situation should be taken into consideration when the WHO selects expert group for preparation of the final version of the Environmental Health Criteria for RF-EMF. Scientists with diverse scientific opinions should and must be appointed in order to facilitate an unbiased scientific debate."

We have sent questions to Van Deventer, but have, to date, received no answer.

Angry Russian letter

Although ICNIRP was recognised as "an official collaborating non-state actor by the World Health Organization (WHO) and the International Labour Organization (ILO)", from the early days, ICNIRP has also been criticized for industry-bias and indisputable situations of conflict of interest.

Hardell notes that the Ethical Board at the Karolinska Institute in Stockholm, Sweden, concluded, already in 2008, that "being a member of ICNIRP may be a conflict of interest that should be stated officially whenever a member from ICNIRP makes opinions on health risks from EMF."

Nevertheless, for the WHO, this does not appear to pose a problem. After the IARC publication in 2011, the WHO announced a new 'formal risk assessment' in 2012, which was launched in 2014 and was then open for public consultation until the end of 2014.

The WHO stated "the drawing of conclusions from the literature and the drafting of these chapters is the remit of a formal Task Group that will be convened by WHO at a later stage in the process."

Hardell disclosed that "it turned out that of the six members in the WHO Core Group, four are active members of ICNIRP and one is a former member." Indeed, in a research paper from 2016, Sarah J Starkey concludes that "the anticipated WHO Environmental Health Criteria Monograph on Radiofrequency Fields, due in 2017, is being prepared by a core group and additional experts, with 50% of those named, being, or having been, members of AGNIR or ICNIRP (Table 2)."

In another research paper, from 2017, Hardell notes: "It is striking how ICNIRP has infiltrated the WHO Monograph core group, making it less likely that the conclusions in that Monograph will differ from ICNIRP's conclusions." And according to him, only one person seems to be independent of ICNIRP and "several persons also have affiliation(s) to other advisory groups, authorities and/or committees. Six of the 20 additional experts are affiliated with ICNIRP".

In March 2017, professor Oleg A. Grigoriev, Chairman and Head of the Scientific Department of Non-Ionizing Radiation, Federal Medical Biophysical Centre of Federal Medical Biological Agency (RNCNIRP) of Russia wrote an angry letter to Maria Neira, Director of Public Health and Environment at the WHO, in which he openly attacks ICNIRP: "It has just come to our attention that the WHO RF Working group consists mainly from present and past ICNIRP members. In general, the WG is not balanced and does not represent the point of view of the majority of the scientific community studying effects of RF. In particular, the private self-elected organization, ICNIRP, similar as majority of the current WHO RF WG members, does not recognize the non-thermal RF effects, which represent the main concern of widespread exposure to mobile communication and upholding guidelines from 1996, which are based on RF thermal effects only."

The Russian scientist concludes that "the guidelines of ICNIRP are irrelevant to the present situation when majority of population over the world is chronically exposed to non-thermal RF from mobile communication. Based on multiple Russian studies and emerging number of studies coming from other countries, the Russian equivalent of ICNIRP has consistently warned against possible health effects from mobile communication. This point of view of RNCNIRP (Russian radiation protection agency) is supported by hundreds of new publications including well known recent RF studies in human and animals."

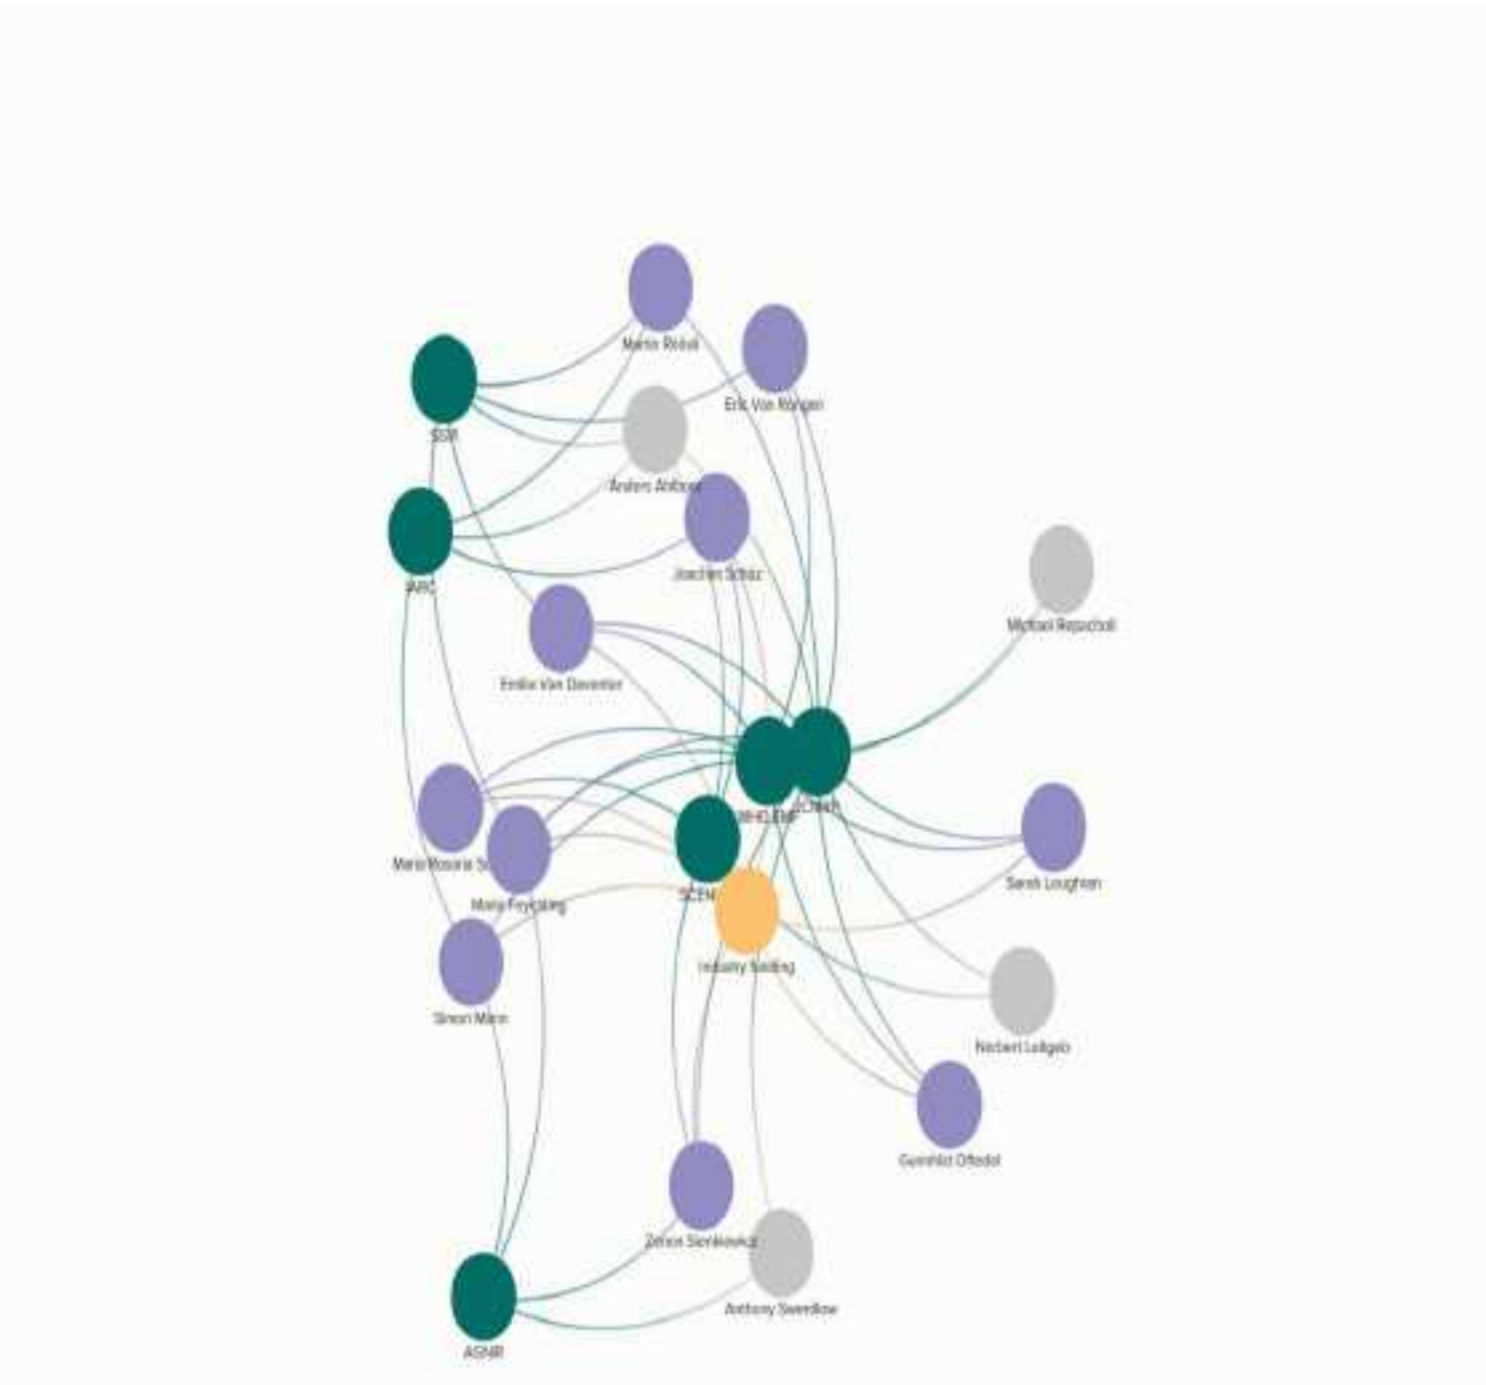
Apparently, this angry Russian letter, in addition to other outcries, did have some effect on the WHO, because it relaunched a Call for Expressions of Interest for systematic reviews (2020) for an 'Environmental Health Criteria Monograph': "The World Health Organization's (WHO) Radiation Programme has an ongoing project to assess potential health effects of exposure to radiofrequency electromagnetic fields in the general and working population. To prioritize potential adverse health outcomes, WHO conducted a broad international survey in 2018. Ten major topics were identified for which WHO will now commission systematic reviews to analyse and synthesize the available evidence."

We wonder if this time the WHO will try to avoid conflicts of interests and whether, for example, there will also be Russian experts and other non-ICNIRP affiliated scientists on the panels of experts.

Investigate Europe wrote that the conflicts in EMF research run deep: "Historically, science in this field has been associated with the telecom sector and the military. ICNIRP's safety limits primarily take into account the needs of the telecom industry, claims Dariusz Leszczynski, former long-time researcher at the Finnish radiation protection agency. In 2011, he sat on the committee of IARC, the cancer body of the World Health Organisation, when it decided that EMF is "possibly carcinogenic" to humans. ICNIRP's goal is to set safety limits that do not kill people, while technology works – so something in between", says Leszczynski."

Dariusz Leszczynski, has written about this many times on his blog and has often referred to an unbalanced expert composition: "ICNIRP can, and should, be considered as a "private club" where, members of the new Main Commission are selected by the members of the outgoing Main Commission. It is a self-perpetuating and self-promoting German NGO that is not accountable for its actions at all. Nobody controls it. Nobody supervises it. Nobody checks it for conflicts of interests. Nobody checks it for the scientific accuracy. In all what and how ICNIRP does, we, the general public, must rely on the self-assurances, from the

ICNIRP, that all is in order. One may ask whether such self-assurances are sufficient when ICNIRP is preparing advisories "enforced" world-wide by the WHO and applied by the numerous governments and by the multi-billion industry."



The following Graphic – made by *Investigate Europe* shows the interlinkages between renowned ICNIRP-members and other scientific bodies. These groups, are to a large extent staffed by the same experts. "Of 13 ICNIRP scientists, six are members of at least one other committee. In the WHO group, this applies for six out of seven," *Investigate Europe* writes.

III - Discussion & Controversies

An observation one could make based on what has been discussed above, is that ICNIRP is simultaneously one of the most powerful and one of the least-known non-governmental organisations (NGO's) in the world. Powerful, because for almost three decades, ICNIRP has enjoyed a monopoly in the regulation of exposure to EMFs through their guidelines thanks to the stamp of approval of the WHO. For the past 30 years, and currently, this advice and these guidelines, are to a large extent followed by governments all over the world. In every annual report, by any major telecom company, you will find references to ICNIRP in any discussion or statement on the safety of their mobile phones. ICNIRP garners huge influence worldwide, functioning on a modest yearly budget of around 140.000 euro, and yet ICNIRP is largely unknown by the general public.

ICNIRP presents itself, and is described by the European Commission and in the media, as an independent commission that gives advice based on scientific evidence. Our research shows that there are several reasons to question this (self)-image.

Biased composition

The composition of ICNIRP is very one sided. As one can read in the portraits of the members of the ICNIRP commission and of the Scientific Expert Group (SEG), they all share the same position on the safety issues: non-ionising radiation only poses a health threat at thermal levels.

Prominent ICNIRP-members therefore denounce the findings of the U.S. National Toxicology Program (NTP) that showed rats and mice contracted cancer when exposed to telephone radiation. In a scientific publication, Van Rongen and co-authors state, as we laid out in the portrait of the former chair of the ICNIRP-commission, that "substantial limitations (of the NTP-study) preclude conclusions being drawn concerning RF EMFs and carcinogenesis."

Professor Hans Kromhout of Utrecht University, who is leading a long-term study into the effects of mobile phone use on human health, and who is chairman of a special committee on Electromagnetic Fields of the leading Dutch Health Council, regrets the way INCIRP minimalizes the conclusions of the NTP study. "You can see that certain groups are trying to reason that away. But they are well-executed studies", he said in a Dutch newspaper.

According to Kromhout, a deep controversy divides the scientific community that researches EMF: "Two camps have arisen in science, with the two groups shouting at each other from their trenches. It has become impossible to conduct a normal conversation." This observation is also made by ORSAA-scientists.

And one of these two camps, is not represented at all inside ICNIRP. "It would seem that the Commission is composed only of 'non-believers," Kromhout wrote in an email to us. In the Dutch newspaper, he had earlier stated: "It's a bit of an opaque club. How candidates are elected is not clear. Call it self-indulgent. In that sense, it doesn't really have an independent status."

In more recent exchanges with us, he re-iterates that the use of the word “self-indulgent” is justified. He refers to the sentence in the ICNIRP Charter: “The election of the members of the Commission shall be made by the Commission from current members of the Commission and from nominations submitted by the Commission itself, the Executive Council of IRPA and the IRPA Associate Societies, with regard to an appropriate balance of expertise. Attention shall be paid to geographical representation.” The first part – that it is the members of the Commission who elect its new members – puts the Commission at risk of remaining a closed circle made up only like-minded scientists.[3]

The unbalanced composition of ICNIRP is further demonstrated by the lack of expert-members with training and experience in medical and/or biological sciences. As one researcher pointed out, of the outgoing ICNIRP commission only one member was trained in medicine, and only three in biological sciences. Furthermore, the sole medical professional, Adele Green, was not an expert researcher in RF-EMR (with a single original research article back in 2005), but was specialised in UV-radiation and skin cancer. She also left ICNIRP in May 2020. It seems a good thing she has been replaced by Dutch scientist, Anke Huss, assistant professor at the Institute for Risk Assessment Sciences (IRAS) at Utrecht University (NL), who seems to be rather critical. Tania Cestari has replaced Adele Green ICNIRP in May 2020, although, like Green that she has collaborated with, her expertise seems to be on UV radiation in dermatology. Interestingly, a search on the PubMed database showed that she has no publications for radiofrequency or other EMFs so she is not an expert on wireless radiation.

The system of cooptation of ICNIRP and the resulting excessively homogeneous composition clearly favors such biases. In 2013, in his article "Not Entirely Reliable : Private Scientific Organizations and Risk Regulation - The case of Electromagnetic Fields", Gabriel Domenech Pascual, Professor Administrative Law at the University of Valencia, states in his conclusions : "That lack of plurality tends to reduce both the quantity and the quality of the available information that serves the basis of their judgments, to stifle critical dialogue, to exacerbate the common biases and positions of their members and to produce extreme outcomes, polarized in the direction of those biases and points of view."

We can safely say that ICNIRP has been, and is still lacking people with a relevant medical background and over represented by physical scientists, which may not be the wisest composition when your remit is to offer advice on human health and safety to governments around the world.

Dr. Chris Portier, former director of the National Center for Environmental Health and international expert in the design, analysis, and interpretation of environmental health data with a focus on carcinogenicity, writes to us that the ICNIRP Council and SEG “appear to have a very wide balance of experience”. However, what they are lacking, according to Portier, “is representation by scientists who have a history of working in risk assessment for chemicals. This leads to their having different risk assessment approaches than the rest of the area.”

[3] For a better understanding of IRPA and functioning of ICNIRP, we refer you to the historical section of this report

Portier argues that risk assessment for chemicals is “well-established and has been used for many, many years”. This standard of assessing risks of chemical substances, governs how to judge the quality of various types of scientific studies and how to incorporate them into the final risk assessment decisions.

Portier: “I have long felt that experts from EMF-research have been incorrectly arguing that this exposure is different and must be handled separately. But ionizing radiation is handled the same was as chemicals in risk assessment, why not EMF?” Portier states that ICNIRP could “expand their expertise in epidemiology and toxicology and experts who understand the challenges of biomedical study design and interpretation in a general sense.

And Portier states that “it would also be good to have a few scientists who are more outspoken about potential risks.” Portier writes that these improvements “would” challenge ICNIRP to “be exact about their dismissal of some of the positive findings” in research on health effect of EMF, that do exist.

The composition of ICNIRP is also one sided in another sense: there is a lack of representatives from the Middle East, Russia, China and India who have outstanding research contributions in the RF research and also (in many cases) have more stringent standards.

For Gabriel Domenech Pascual "this lack of plurality is not fortuitous at all, but caused by the system used to elect the members of the ICNIRP. As everybody knows, cooptation tends to produce homogeneous, conservative, immobile and not sufficiently innovative groups."

"This stands in sharp contrast with the principles underlying current European Union Law", Domenech Pascual adds. "As stated in the Communication from the Commission on the collection and use of expertise, pluralism is a determinant of the quality of the scientific advice. Therefore, “wherever possible, a diversity of viewpoints should be assembled. This diversity may result from differences in scientific approach, different types of expertise, different institutional affiliations, or contrasting opinions over the fundamental assumptions underlying the issue. Depending on the issue and the stage in the policy cycle, pluralism also entails taking account of multi-disciplinary and multi-sectorial expertise, minority and non-conformist views".

Various EMF-experts have pointed out on many occasions in the past years that ICNIRP is wrongfully dismissing certain scientific studies showing adverse health effects and sticking, in an almost dogmatic way, to the conviction that “non-ionising radiation poses no health threats and the only effects it has are “thermal”. Two leading experts, Kromhout and Portier confirm to us that ICNIRP is a closed, non-accountable and one-sided organisation. As concluded earlier, “a closed circle of like-minded scientists” has turned ICNIRP into a self-indulgent science club, with a lack of biomedical expertise as well as a lack of scientific expertise in risk assessment and risk management philosophies (similar to those used for ionizing radiation and for chemicals), which might lead to “tunnel-vision”.

Will world safety standards really be safe?

Several ICNIRP-members are, or were, also members of the International Committee on Electromagnetic Safety (ICES) of the IEEE. This is an organisation in which many people from the media and telecom industry and from the military are actively and openly involved. The former chair of the ICNIRP-commission was a member of an ICES-committee. As we mentioned in his portrait, ICES thanked Van Rongen for improving the relationship between ICES and ICNIRP and for his willingness to discuss the harmonisation of ICNIRP-guidelines and IEEE-exposure limits. In its latest published annual report (2016), ICES states: "ICES will maintain its collaborative relationship with ICNIRP with the goal of setting internationally harmonized safety limits for exposure to electromagnetic fields at frequencies below 300 GHz. This interaction with ICNIRP is considered a major step forward."

In 2016 Van Rongen invited members of ICES to give their comment on the new guidelines for HF Fields. And ICNIRP took these comments very seriously. In 2017 during the annual meeting of ICES it was stated that "ICNIRP has delayed finalizing their conclusions to give full consideration of ICES's recommendations".

The new chair of the ICNIRP-commission Croft was also member of ICES until December 2015. Seven other ICNIRP-scientists - Guglielmo d'Inzeo, Akimasa Hirata, Jose Gomez-Tames, Ilkka Laakso, Kensuke Sasaki, John Tattersall and Tongning Wu – were or are also members of an ICES-committee.

This clearly shows that ICNIRP has been working very closely with IEEE/ICES on the creation of the new RF safety guidelines that were published this year. And this implies that large telecom-companies as Motorola and others, as well as US military, had a direct influence on the ICNIRP guidelines, which are still the basis for EU-policies in this domain.

Kromhout comments that he was unaware of the fact that several ICNIRP-members also participate in ICES/IEEE. ICES/IEEE is not one of the organisations that is mentioned as a collaboration partner on the ICNIRP-website. On the subject of the IEEE, the Dutch professor writes that "this is not really an independent organisation when it comes to electromagnetic fields and health."

Portier sees the membership of ICES as a potential conflict of interest. He indicates as an example that the declarations of interests of some ICNIRP-members mention membership in ICES, but no mention of the travel costs associated with that membership being covered by ICES: "This has two consequences. Travel cost reimbursement is a perk and it could be removed if the member fails to give the right answer, hence a potential Conflict of Interests. Secondly, being a member in ICES gives industry access to the ICNIRP member which would not be available to the general public and can thus bias opinions."

A membership of and close cooperation of ICNIRP-members with ICES, which for several years held its annual meetings at a Motorola's branch, can be considered as a possible conflict of interest. As described, during the current leadership of ICNIRP, these ties got even closer "with the goal of setting internationally harmonized safety limits for exposure to electromagnetic fields".

Ties that bind

A lot of ICNIRP-scientists have also participated in research work that was funded, or partly funded, by the telecom industry.

The International Agency for Research on Cancer (IARC) has a strict policy when it comes to inviting scientists to assist it in the writing of the famous monographs – like the one from 2011, that classified radiofrequency electromagnetic fields as, "possibly carcinogenic to humans (Group2B), based on an increased risk for glioma, a malignant type of brain cancer associated with wireless phone use." In the final Monograph 2012 report, it is stated that each scientist must disclose pertinent research, employment, and financial interests during the past 3 years, unless that a grant from for example a company does not exceed more than 5% of total research budget: "All grants that support the expert's research or position and all consulting or speaking on behalf of an interested party on matters before a court or government agency are listed as significant pertinent interests."

In our introduction, we wrote that the European Food and Safety Authority (EFSA) has slightly less stringent member-selection criteria: "Research funding from the private sector benefiting EFSA's experts should not exceed 25% of their total research budget."

It seems that this percentage is not exceeded by most of the members of the ICNIRP-commission and Scientific Expert Group, insofar as we can trust their Declarations of Personal Interest. But these declarations are often not complete. Anssi Auvinen, for example, mentions that he received € 100,000 from the Mobile Manufacturers Forum for the Finnish section of the COSMOS-study. But he does not mention what percentage of his total research budget that amount constitutes. And Maria Feychting, former vice-chair of the ICNIRP-commission, did not mention any research support received from commercial entities in her Declaration of Personal interest, although a lot of her research actually was, as we showed in her portrait, funded by industry. Some of the member's DOI's are also somewhat out of date. For example, the last DOI available for Isabelle Lagroye, published on the ICNIRP-website, is dated October 2015.

The majority of ICNIRP-scientists did perform research partly funded by industry. But is this important information? As we argue in the introduction, we believe it is. Scientific publications, co-authored by two ICNIRP-scientists – Anke Huss and Martin Röösli, confirm the importance of funding. In 2006 and 2009 they did a systematic review of the effect of the source of funding in experimental studies of mobile phone use on health, and their conclusion was that, "industry-sponsored studies were least likely to report results suggesting (adverse health) effects".

And theirs is not the only study that showed this kind of bias. Portier agrees in writing to us that this is a problem: "There have been numerous studies of the differences in reporting from industry-funded research versus publicly-funded research that suggest a strong bias."

David O. Carpenter, professor of Environmental Health Sciences at the University at Albany, explains the mechanism behind this claim in the preface of the book Corporate Ties That Bind - An Examination of Corporate Manipulation and Vested Interest in Public Health: "One of the greatest problems in scientific discovery," he writes, "is the perversion that can result due to conflicts of interest. While there are other possible bases for conflicts of interest, most are financial. Individual scientists may have financial conflicts of interest that influence the design of the studies they perform so that they obtain a result similar to that which they, or their funders, want. When funding for scientists comes from an organization or corporation with desires to present a clean bill of health to the public, there is strong motivation to give the funder what they want, if only to continue receipt of funding."

The Australian researcher, Don Maisch, claimed in his PhD-thesis, *The Procrustean Approach: Setting Exposure Standards for Telecommunications Frequency Electromagnetic Radiation* (2010), that the dismissal by ICNIRP of all studies that show health effects of non-ionizing radiation shows the influence industry exercises on ICNIRP: "Such dismissal may, on the surface, appear to be objective expert opinion, but an examination of ICNIRP's risk assessment processes finds, however, that power industry influence is endemic to the process. This influence appears to be aimed at ensuring economic protection for the industry against the need to spend enormous amounts of money on upgrading distribution networks as well as the risks of litigation if more restrictive limits were ever put in force.**"**

According to Maisch, the essence is that the thermal limitations of the IEEE standards and the ICNIRP RF Guidelines "can be said to be little more than an outdated artefact from a half-century ago, maintained by a scientific elite who have long staked their scientific credibility on maintaining that viewpoint. From their perspective, to retreat from that paradigm would be to admit that they had it wrong after all."

Ten years after Maisch' publication and many other similar criticisms, ICNIRP still adheres to the paradigm that the only proven effects are thermal. "ICNIRP appears to take into account only the warming of tissue and uncontrolled muscle contractions, although they claim in the most recent advice, that they also evaluated other mechanisms", writes Kromhout.

As many scientists and critical observers have pointed out, it seems as if ICNIRP members are either oblivious or ignoring scientific studies that find possible adverse health effects where there is an absence of heating. Even when some ICNIRP-members themselves acknowledge that industry-funding of scientific research tends to have less positive findings, and publicly funded studies – like the NTP-study – does find significant links between EMF and adverse health effects, this does not seem to influence one iota the views of ICNIRP-members.

A mixed bag of responsibilities

In an e-mail we received from Lloyd Morgan, Senior Research Fellow of the Environmental Health Trust and Director of the Central Brain Tumor Registry of the United States, is very critical of both ICNIRP and governments: "Who are ICNIRP? The International Committee on Non-Ionising Radiation Protection (ICNIRP) are a private, self-appointed body or NGO who together with the Advisory Group on Non-ionising Radiation (AGNIR) and Public Health England (PHE), have somehow ended up effectively setting microwave radiation exposure 'safety' standards for the populations of large parts of the world since the 1990s," he writes. "What amazes me, and simultaneously sickens me, is how did ICNIRP convince a large number of "independent" nations to adopt ICNIRP's so called "standards"?

Morgan suspects that high-level persons in the government's administration was "able to have the legislation passed because almost no-one in the government understood what was happening."

ICNIRP only publishes guidelines. It is then up to national governments to decide if they pass these guidelines into law. According to Lloyd Morgan, "that places the burden on each national government, should its citizens file a lawsuit".

Clearly, the Telecom sector as a whole, and the auctioning off of bandwidth and selling of Telecommunication licenses, are an important source of cash income for governments. The analogy with the Tobacco sector has often been made by scholars who study 'regulatory capture', but there is also an important similarity between the tobacco and telecom sectors in terms of their importance for State budgets.

The auctioning off of Radio frequency spectrums brings in billions of euros for European countries. Telecom companies also earn billions of euros thanks to these spectrum acquisitions, since 'owning the right' to use a specific radio frequency spectrum is an essential resource for telecommunication services such as mobile telephones, TV and radio broadcasting, satellite and broadband communications.

The *European 5G Observatory* notes that, "Germany's Federal Network Agency announced that the 5G auction, which started in March 2019, ended with 6.55 billion euros offered in total by the four bidders. *Deutsche Telekom* and *Vodafone* Germany criticized high prices of the country's auction". In the 5G Action Plan as adopted by the EU in 2016 it says:, "from September 2016, member states will be required to authorise the 700 MHz-band by 2020, unless there are justified reasons for delaying it until mid-2022 at the latest", reports the *European 5G Observatory*. The Observatory also stated, in April 2020, that "exceptional circumstances caused by the Covid-19 epidemic have forced some countries in Europe to postpone 5G auctions scheduled in the first months of 2020. Four EU countries, Austria, France, Spain and Portugal have postponed spectrum auctions for 5G due to the Covid-19 epidemic so far."

The European Commission selected the consultancy firm, Idate-digiworld to carry out the *European 5G Observatory,* to monitor the rolling out of the 5 G Action Plan. IDATE-DIGIWORLD is a smart-looking consultancy company and self-declared "European think-tank for members, policy-makers and players of the digital transformation", with some of the largest telecom operators and producers as its clients.

One of those clients, isn't a Telecom giant, but a governmental regulator, Ofcom in the UK. *European 5G Observatory* reports that 'Ofcom opened a consultation on human exposure to Electromagnetic Field Emissions (EMF) in the UK. The consultation started on February 21th 2020 and ended on May 15th 2020: "The regulator proposes to include a specific condition in telecom licences requiring licensees to comply with ICNIRP guidelines. {…) At the same time, Ofcom released the results collected close to 16 5G base stations in 10 cities across the UK and to 60 GHz fixed wireless equipment in Liverpool. In all cases, the measured EMF levels from 5G base stations were far below the ICNIRP Guidelines (the highest level was approximately 1.5% of the relevant level); the 5G share of the total emissions level observed was currently very low."

To the question, "Is ICNIRP responsible?", Paolo Vecchia, former Chairman for ICNIRP (2004-2012) answered very clearly at a conference in September 2008 that "the ICNIRP guidelines are neither mandatory prescriptions for safety, the "last word" on the issue, nor are they defensive walls for Industry or others." This statement makes it clear that the decision to adopt these guidelines into national legislation as "sufficient to protect public health" is political. The possible misuse by governments of ICNIRP and its guidelines seems to be another key question, that still needs looking into and answering.

On the other hand, ICNIRP presents itself as the provider of scientific truth. For example, in a report for the Irish government, under the heading, "Recommendations International Guidelines" it states that "there should be strict compliance with ICNIRP guidelines: The ICNIRP guidelines on exposure limits have been recommended by the European Commission to its Member States, and they provide science-based exposure limits that are applicable to both public and occupational exposure from RF and ELF fields. They also provide sound guidance on limiting exposure from mobile phones and masts, as well as for power-line fields. The ICNIRP guidelines provide adequate protection for the public from any EMF sources. While the guidelines were published in 1998, they are constantly under review and still have appropriately protective limits. The guidelines are based on a weight of evidence review from all peer-reviewed scientific literature and not on the conclusions of any single scientific paper."

Even as ICNIRP has been positioning itself during the last 25 years as the sole scientific truth when it comes to possible relation between EMF and adverse health effects, it would not be correct to hold this scientific NGO accountable if one day it would be undisputed that EMF causes health problems. National governments have their own responsibility to protect their citizens, just as the European Commission has, which after all is the 'Guardian of the Treaty' and therefore should also take the legally binding 'precautionary principle' into account.

The telecommunication industry applauds ICNIRP

In most policy fields, industry keeps reiterating that the limits scientific advisory committees propose are too strict. But in the case of the exposure limits for non-ionizing radiation the telecom industry seems very content with the norms ICNIRP proposes. In many reports over the past twenty years, the Telecoms lobby in Europe has always referred to the safety assurances published by ICNIRP.

In its Environmental Report of 2005, the European Telecommunications Networks Operators' Association (ETNO) wrote: "Concerning the European Union's legislative and policy framework on EMF, ETNO has been in direct contact with EU institutions. The association has provided a steady stream of facts and advice to legislative bodies in order for the EU to base its Directive concerning 'minimum health and safety requirements regarding the exposure of workers to the risks arising from physical agents (electromagnetic fields)' on a sound scientific basis as provided by the International Commission on Non-Ionising Radiation Protection (ICNIRP)."

Thirteen years later, the Boston Consulting Group, in a report with the ominous title, 'A playbook for accelerating 5G in Europe', pleads for the harmonized limits ICNIRP (and also IRPA and the WHO EMF project) proposes, and criticizes governments that apply stricter limits. Exactly the same point was made by ETNO in a public consultation by the European Commission. ETNO was in favour of the "harmonised ICNIRP limits".

The same word, *harmonised*, comes back in a plea for "a harmonised EU approach to 5G security" that ETNO launched on 29 January 2020. "We therefore welcome today's publication of the "5G Security Toolbox", presented by EU Member States with ENISA and the European Commission. Europe's decision-making on 5G should continue being based on facts, it should be proportionate to threats and build on a solid understanding of technology reality. In this context, we invite National Governments to avoid disproportionate actions that negatively impact the investment climate, and which could in turn harm both Europe's competitiveness and its strategic position in 5G development."

ETNO argues that rules and regulations should not hamper but support European investment and innovation, because "regulatory pressure still risks holding back European investment and innovation on many fronts"…"The speed of 5G rollout is significantly slowed by excessive spectrum prices and challenging license conditions."

ETNO continues to explain the policy-wish list: "The opportunity of fully unleashing fibre deployment awaits a pro-investment implementation of the European Electronic Communications Code. Regulatory asymmetries, especially in the field of data, still hold back European innovation. Market fragmentation still affects Europe's full potential in network investment. European institutions and national governments both have a major role to play in removing such barriers."

Yet again, ETNO does not lobby for lowering the ICNIRP standards, these are not seen as part of the "regulatory pressure" that hampers technological development. On the contrary: the norms ICNIRP proposes are the "harmonised limits" that ETNO welcomes.

All in all, the telecom-sector seems to be quite pleased with ICNIRP's positioning. This is deviating from the standard procedure in EU-policy making where a specific industry concerned will on essential aspects always try to influence laws and regulations in their favour through various ways of lobbying. Apparently in case of ICNIRP there is simply no need to do so.

The Telecom Lobby

In order to promote a continuation of favourable policy-making, European telecom companies have many lobby-meetings with the European Commission, and no doubt also at national political levels. According to the EU transparency Register, ETNO has a budget of over one million euros for lobbying and representing Europe's telecom companies. With at least seven registered lobbyists, ETNO had 70 registered lobby meetings with the European Commission (EC) in 2019. "ETNO's primary purpose is to develop top-level policy papers and support members in promoting a positive policy environment allowing the EU telecommunications sector to deliver best quality services to consumers and businesses. We also organize some of the main European events for discussing telecom and digital policy."

But of course, the individual telecom companies also have lobbying budgets and lobbyists representing them at the European institutions in Brussels. Ericsson had a lobby budget of 700.000 euros and five accredited lobbyist in 2019, Telefonica had a lobbying budget of 1,8 million euros and 6 lobbyists who covered no less than 83 meetings with the EC, Deutsche Telekom had a 1,5 million lobbying budget, with 5 lobbyists and a total of 110 lobby meetings with the EC.

In early December 2019, a large delegation of CEOs from ETNO met with Margrethe Vestager, Executive Vice-President of the European Commission responsible for "Europe fit for the Digital Age". The delegation included: Tim Hoettges from *Deutsche Telekom*, Stephane Richard from *Orange*; Thomas Arnolder from *Telekom Austria*, Salvatore Rossi from *TIM*, Alexandre Fonseca from *Altice Portugal*, as well as the Chairman of ETNO, Steven Tas, the Director General of ETNO, Lise Fuhr, and senior representatives from *Telefonica* and *Telenor*.

At the end of January 2020, an important event was held, the European 5G conference. It welcomed more than 250 delegates, who discussed "the necessary next steps to ensure the success of 5G in Europe". Eric Van Rongen, at the time still ICNIRP-Chair, was among the speakers who provided "the audience with insightful views on their areas of expertise." The purpose, apparently, was not to discuss the sagacity and safety of rolling out 5G, but rather to ensure the success of 5G deployment.

It is important to note that the efforts of the telecom industry to influence regulatory agencies often take illegal forms. Telecommunications companies are high on the list of the companies that were penalised in the U.S. for corrupt practices. European companies like *Ericsson, Alstom* and *Telia* are in the top ten.

Also significant, is the fact that more and more world leading insurance companies are backtracking from insuring telecom companies concerning the risks around EMF. In March 2019, in its "SONAR Emerging risk insights" report, one of the world's largest insurance companies, *Swiss Reinsurance Company* (Swiss Re), classified "unforeseen consequences of electromagnetic fields" into the highest risk class, together with endocrine disrupting chemicals. "The ubiquity of electromagnetic fields (EMF) raises concerns about potential implications for human health, in particular with regard to the use of mobile phones, power lines or antennas for broadcasting. Over the last decade, the spread of wireless devices has accelerated enormously. The convergence of mobile phones with computer technology has led to the proliferation of new and emerging technologies. This development has increased exposure to electromagnetic fields, the health impacts of which remain unknown."

The lobby power of the telecom-industry in Brussels, the decision-making heart of the EU, is enormous. Yet the corporations involved do not have to lobby the guidelines and health advice related to their technology, because ICNIRP has been providing the "safety certification" for over 25 years. At the same time the insurance sector is not very assured and does not want to pay possible litigation costs once telecom companies would get sued, which is happening more and more frequently.

The call for more independent scientific assessment in this area

Almost ten years ago, in May 2011, the Council of Europe adopted a report from Mr Jean Huss on "The potential dangers of electromagnetic fields and their effect on the environment". It stated that the findings of scientific research on the possible risks of electromagnetic fields were inconclusive and contradictory. In the light of the correlation between origin of funding and the findings it called for "genuine independence on the part of the expert appraisal agencies and for independent, multidisciplinary and properly balanced expert input. There must no longer be situations where whistle blowers are discriminated against and renowned scientists with critical opinions are excluded when experts are selected to sit on expert committees or no longer receive funding for their research."

In the meantime, not a lot seems to have changed. In a letter, published this year in *Bioelectromagnetics,* three researchers - Steven Weller , Victor Leach and Murray May - of the Australian "Oceania Radiofrequency Scientific Advisory Association" (ORSAA) write: "Half a century of scientific research into the safety of EMFs (from static to 300GHz) has not resulted in any substantial policy advice changes. The question that we believe needs to be asked is as follows: Is the continuing unchanged policy advice on EMFs occurring because those who are trying to advocate change have no voice in the process and because the process is dominated by groups with self-interests in maintaining the status quo?"

The three researchers point to the fact that radiofrequency electromagnetic radiation is "a booming multi-trillion-dollar industry globally, and changing current prescribed safety levels to more stringent standards would bring about unfavourable financial consequences and affect industrial and military functions. In some countries, such as Australia, the regulator, which has a health protection responsibility, also sells RF spectrum licenses, which represents a clear conflict of interest. The very same agencies with responsibility for providing safety advice to the public are also considered by some to have been captured by the industry."

The huge financial weight and power of the telecom companies is something the industry itself also stresses. In its report from January 2020, 'The State of Digital Communications 2020', ETNO boasts that "its Telecom members are thriving and business is booming: Telecom is Europe's major technology business, with a €136.9 billion per year value added and training on the rise. (…) Of the 17 Europe-based companies figured in the 2019 Forbes Digital 100 index, 11 are either telecoms operators or telecoms equipment vendors, and more than half of them are ETNO members."

Whether or not ICNIRP is 'captured by industry', a remarkable fact is that the organisation that appears to be the world's most important body responsible for advice on non-ionizing radiation is a private organisation, not a public authority.

"To me it seems wiser if the EU and national governments stop relying only on the advice of ICNIRP. A committee of its own is not an unnecessary luxury," Hans Kromhout writes. When we ask him if it would seem to him more logical that it be a public organisation giving advice on non-ionizing radiation, he answers: "I completely agree."

But this is not what is happening in the heart of the European Union. According to ICNIRP's website there is a contractual partnership between the European Commission, which is the Guardian of the Treaty, and thus also of the legally enshrined precautionary principle. It states: "The European Commission and ICNIRP collaboration over the years, relies on annual or specific contracts, such as the Concerted Action within FP5 - Life Quality, Key action Environment and Heath. ICNIRP also takes part, in consultation together with other stakeholders, on the development of directives and liaises, upon request, with different EC entities, such as the Scientific Committee on Emerging and Newly Identified Health Risks (SCENIHR). Support to ICNIRP is provided by the European Commission through its Directorate General Health and Safety at Work as part of an EC grant agreement, as laid down in the ICNIRP reports."

Given the experience with ICNIRP of the past 25 years, the growing body of evidence that there are serious concerns on adverse effects of EMF on public health and the huge economic interests involved, it seems not very wise for the European Commission and national governments to base their policies solely on the ICNIRP guidelines and advice.

Chris Portier agrees by saying that “governments have no say in the governance or membership of ICNIRP. In addition, without their own review committees, governments do not have their own experts to advise them about these topics. I believe it would be best if such an entity was run by a trusted organization that has some form of government oversight.”

Portiers adds in writing to us: “I have been in the position of managing, running, chairing and/or being a member of dozens of national and international committees. These were always government committees or WHO-related entities. When run properly, governments can get excellent advice on issues. There is usually a place for interested parties (industry, concerned citizens) to express their opinions to these committee members at public forums. And there are legal consequences to providing false information on Conflict of Interest forms, etc. All of these reasons lead one to believe a government managed Commission would be better.”

We think that the call for more independent scientific assessment in this area is, for all the arguments mentioned in the above, fully justified.

IV - Conclusion

ICNIRP presents itself, and is described by the European Commission and in the media, as an independent international commission that gives advice based on scientific evidence. We believe that there are various reasons to question this (self)-image.

The composition of ICNIRP is very one sided. With only one medically qualified person (but not an expert in wireless radiation) out of a total of 14 scientists in the ICNIRP Commission and also a small minority of members with medical qualifications in the Scientific Expert Group, we can safely say that ICNIRP has been, and is still, dominated by physical scientists. This may not be the wisest composition when your remit is to offer advice on human health and safety to governments around the world.

As one can read in the 45 portraits of the members of the ICNIRP commission and of the Scientific Expert Group (SEG), they all share the same position on the safety issues: non-ionising radiation poses no health threats and the only effects it has are thermal. ICNIRP says "non-ionising radiation poses no health threats if it does not heat the tissue by more than 1 °C", by which it admits that there are possible health effects, but only if exposure levels to strong radiation are too high".

Over the past years, and on many platforms, various EMF-experts have stated that ICNIRP is wrong to continue dismissing certain scientific studies showing adverse health effects – like the American NTP-study - and is mistaken in its almost dogmatic conviction that "non-ionising radiation poses no health threats and the only possible health effects it has are thermal in case of strong radiation".

Even after much criticism from members of the global scientific community, ICNIRP still adheres to the paradigm that the only proven effects (on health) are thermal. "ICNIRP appears to take into account only the warming of tissue and uncontrolled muscle contractions, although they claim in the most recent advice, that they also evaluated other mechanisms", writes Dutch Professor Hans Kromhout, who is currently leading a long-term study (in the Netherlands) into the effects of mobile phone use on human health, and who is chairman of a special committee on Electromagnetic Fields of the leading Dutch Health Council, which advises the Dutch government.

It seems that "a closed circle of like-minded scientists" has turned ICNIRP into a self-indulgent science club, with a lack of bio-medical expertise, as well as a lack of scientific expertise in specific risk assessments. Thereby, creating a situation which might easily lead to "tunnel-vision" in the organisation's scope. Two leading experts, Hans Kromhout and Chris Portier, confirmed to us that ICNIRP is a closed, non-accountable and one-sided organisation.

As many scientists and critical observers have pointed out, it seems that ICNIRP members are either oblivious to, or are ignoring, scientific studies that find possible adverse health effects in the absence of heating. Even though some ICNIRP-members have themselves acknowledged that industry-funded scientific research tends to produce less findings showing adverse health effects of EMF, whereas publicly funded studies – like the NTP-study – do find significant links between EMF and adverse health effects, this does not seem to influence one iota the views of ICNIRP-members.

The majority of ICNIRP-scientists have done, or are doing, research partly funded by industry. Is this important? As we argue in the introduction, we believe it is. Scientific publications, co-authored by two ICNIRP-scientists – Anke Huss and Martin Röösli, confirm the importance of funding. In 2006 and 2009 they did a systematic review of the effects of the source of funding in experimental studies of mobile phone use on health, and their conclusion was that, “industry-sponsored studies were least likely to report results suggesting (adverse health) effects”. And theirs is not the only study that showed this, as there have been numerous studies of the differences in reporting from industry-funded research versus publicly-funded research that suggest a strong funding bias on the results.

In addition to the fact that certain members of ICNIRP, are simultaneously members of the International Committee on Electromagnetic Safety (ICES) of the US-registered Institute of Electrical and Electronics Engineers (IEEE), we have seen further evidence of a close cooperation between ICNIRP and ICES, an organisation in which many people from the media and telecom industries, as well as from the military, are actively and structurally involved. During the current leadership of ICNIRP, these ties have become even closer “with the goal of setting internationally harmonized safety limits for exposure to electromagnetic fields”. This must surely be considered as a situation in which conflicts of interest are a real possibility.

It is clear from ICES minutes that ICNIRP worked very closely with IEEE/ICES on the creation of the new RF safety guidelines that were published in March 2020. And this implies that large telecom-companies such as Motorola and others, as well as US military, had a direct influence on the ICNIRP guidelines, which are still the basis for EU-policies in this domain.

Although there is a lot of lobby-power by the telecom sector in the European Union (both in Brussels and in the member states), the European Telecommunications Networks Operators' Association (ETNO) does not lobby for lowering the ICNIRP standards, as these are not seen as part of the “regulatory pressure” that hampers technological development. On the contrary: the norms ICNIRP proposes are the “harmonised limits” that ETNO welcomes. All in all, the telecom-sector seems to be quite pleased with ICNIRP's positioning. This deviates from the standard procedure in EU-policy making, where a specific industry concerned will, on essential aspects, always try to influence laws and regulations in its favour through various lobbying strategies. Apparently, in the case of ICNIRP, there is simply no need to do so. At the same time, the insurance sector does not, at present, seem very reassured and does not want to be put in a situation of having to pay potential litigation costs, if and when telecom companies get sued, something that is happening more and more often.

Despite ICNIRP positioning itself, during the last 25 years, as the sole purveyor of scientific truth when it comes to possible relation between EMF and adverse health effects, it would not be right to hold this scientific NGO solely accountable if, one day, it were to become undisputed that EMF do cause health problems. National governments, as well as the European Commission, which is, after all, the ‘Guardian of the Treaty’, have a duty of care and protection of their citizens, and therefore should also take the legally binding ‘precautionary principle’ into account.

We think that the call for more independent scientific assessment in this area is, for all the arguments mentioned above and in what follows, fully justified.

That is the most important conclusion of this report: for really independent scientific advice we cannot rely on ICNIRP. The European Commission and national governments, from countries like Germany, should stop funding ICNIRP. It is high time that the European Commission creates a new, public and fully independent advisory council on non-ionizing radiation. The funds currently allocated to ICNIRP could be used to set up this new organisation. And given the overall rise in R&D funding via Horizon Europe, with a foreseen budget (for 2021-2027) of between 75 and 100 billion euros, funding should in no way constitute an insurmountable hurdle to setting up this new, truly independent, body.

V - PORTRAITS OF THE ICNIRP-MEMBERS

ICNIRP COMMISSION:

Gunde Ziegelberger (Scientific Secretary)

Biography

On ICNIRP's website we read that Gunde Ziegelberger holds a PhD in Biology and after a career at the Max-Planck-Institute, she joined the Federal Office for Radiation Protection (BfS) in 2002, where she works on "Non-Ionizing Radiation". Since 2004 she also worked as Scientific Secretary for ICNIRP- she replaced Rüdiger Matthes, who became a commission member - and in that function, she is also a member of the ICNIRP Board together with the Chair (see Croft) and Vice Chair (see Van Rongen). ICNIRP's website clarifies: "The three Board members represents ICNIRP externally and mostly in its relations with the international and national partners and the press. The Scientific Secretariat is in charge with some specific scientific projects mostly related to workshops and with all administrative and operational tasks."

Position

In February 2019 Dr Ziegelberger gave a short interview in which she stated that when the limit values are respected so far scientific findings show that human beings don't run any risk from electromagnetic radiation.

Ziegelberger functions as Scientific Secretary of ICNIRP, she co-authors many scientific publications with ICNIRP-members. In September 2016 for example Ziegelberger was co-author of a publication 'A Closer Look at the Thresholds of Thermal Damage: Workshop Report by an ICNIRP Task Group'. The article concludes the workshop – co-organsied by the WHO and financed by the European Commission, the Turkish Ministry of Health, the International Radiation Protection Association (IRPA), the German Federal Ministry for the Environment (BMUB), and the Finnish Radiation and Nuclear Safety Authority (STUK). The conclusion shows that the workshop "will provide valuable input into the revision of the guidelines being formulated by ICNIRP for limiting human exposure to RF fields." It was also clear that only thermal (adverse) effects were discussed as was the case in the new ICNIRP guidelines from 2020.

She co-authored as BfS -researcher a study within the ARIMMORA risk assessment which concluded that "the relationship between exposure to the agent ELF-MF and risk of childhood leukaemia is considered consistent with "IARC Group 2B" classification of possibly carcinogenic to humans (Fig. 1). This category is the result of limited evidence of carcinogenicity in humans and inadequate evidence of carcinogenicity in experimental animals."

Possible conflicts of interest.

Although Ziegelberger plays an important role for ICNIRP, given her position in the board and the fact that she works in an important department for radiation protection (BfS) of the German government, we could not find any DOI.

Rodney Croft (chair as of May 2020)

Biography

Rodney Croft is a psychology researcher. He works as professor of Health Psychology at the School of Psychology, University of Wollongong, Australia.

He joined the ICNIRP Biology Standing Committee in 2008 and the Main Commission in 2012, to become chair in May 2020.

ICNIRP's website states that his research focuses on the delineation of human brain function, as well as psychiatry more generally. He participates in a variety of national and international scientific and government committees, was Executive Director of the Australian Centre for Radiofrequency Bioeffects Research ((ACRBR 2004-2011) and is currently Director of the Australian Centre for Electromagnetic Bioeffects Research.

In June 2011, Rodney Croft as Executive Director of ACRBR announced that the organisation would cease operations because "it had been unable to secure further funding to continue its research activities". But many of the ACRBR Directors would be able to continue their Rf research but under the banner of the Bioelectromagnetics Research Group, part of the Brain and Psychological Sciences Research Centre (BPsyC) at the Swinburne University of Technology, which has for many years very close ties to Telstra, Australia's biggest Telecom company.

In August 2012 Croft received new funding when Australian Minister for Health, Tanya Plibersek, announced the establishment of a new $2.5 million NHMRC Centre of Excellence: the Australian Centre for Electromagnetic Bioeffects Research (ACEBR) to be based at the University of Wollongong and led by Professor Croft. One of the central university partners of the ACEBR research Swinburne University.

Position

Croft is a typical ICNIRP member and has been defending for years and from different positions the point of view that there are no dangers associated with the use of mobile phones. On the ABC Lateline program (April 4, 2009) Dr. Rodney Croft, then Director of ACRBR, stated: "There really has been a lot of research done to date and the research has very clearly shown that there aren't any effects. With children, I really don't think there is any evidence suggesting that this might be a problem. There isn't anything to suggest that we may have to be a little bit more cautious."

Much earlier in 2003 the Australasian College of Nutritional and Environmental Medicine (ACNEM) published a paper by Don Maisch "that detailed reasons why extra precautions needed to be taken for children and cell phone use. The paper included a number of statements of concern specific to this issue from scientific and medical organizations internationally and concluded with the question: “Is it worth the risk” to continue to allow unrestricted cell phone use by children.”

In 2008 the Russian National Committee on Non-Ionising Radiation Protection (RNCNIRP) issued official advice that the “health of the present generation of children and future generations is under danger” from cell phone use and therefore the committee has recommended that cell phone use be restricted for people under 18 years of age.

Croft said in 2011: “With children, I really don’t think there is any evidence suggesting that this might be a problem. There isn’t anything to suggest that we may have to be a little bit more cautious” And to visually back up ACRBR’s on children and cell phone use on the ACRBR web site published “an animated image that included images of children happily using cell phones”.

In 2009 a scientific review paper with Van Rongen and Croft as first and second authors respectively stated. “Subjective symptoms over a wide range, including headaches and migraine, fatigue, and skin itches, have been attributed to various RF sources both at home and at work. However, in provocation studies a causal relation between EMF exposure and symptoms has not been demonstrated, suggesting that psychological factors such as the conscious expectation of effect may play an important role in this condition.” The article mentions that “all authors are either current or former members of the Standing Committee on Biology of the ICNIRP” but does not mention anything on funding of the study.

During an International Workshop on RF Measurements, Research Studies & Standards Development in 2018 Croft downplays scientific research that shows effect from EMF by saying that “Counterbalancing is necessary to enable appropriate interpretation of data” and “Conclusions must be based on the scientific literature, not just a data set”.

In 2019, Croft and a researcher (expert in antipsychotics) were awarded 1.2 Million$ for a project entitled "Exposures of mobile phone radiofrequency electromagnetic energy in juveniles: effects on brain development and behaviours." Neither of the two researchers are experts in the area of brain development, developmental psychology or juvenile behaviour.

Within ICNIRP, Rodney Croft was the chair of the Project Group that was tasked with preparing the new ICNIRP Guidelines, published early 2020. According to critics, ICNIRP still dismisses completely: the existence and significance of non-thermal effects, existence of the risk of cancer in long term avid users of mobile phones, IARC’s classification of RF as a possible human carcinogen (the IARC monograph review of science was not included in list of science reviews used by ICNIRP in preparation of the new guidelines).

Possible conflicts of interest

Just like his predecessor Van Rongen, Rodney Croft provides unpaid services to the IEEE ICES SC/4 Standards committees, a US version of ICNIRP, with a broad number of representatives from both military and telecom industry; ICES boasted that they had “at least two members of ICES as members of the new 13 person ICNIRP Project Group (PG) on HF guidelines (up to 300 GHz), of which the PG Chairman (Croft), is now very willing to work with ICES to develop science based safety standards. This will enhance the possibility of harmonizing international RF safety standards."

Croft also advises the EMF reference group, and a community group managed by the Australian Government organization, ARPANSA. He receives funding from the Electric Power Research Institute EPRI for a project investigating RF effects on EEG and thermoregulation.

To possibly answer this question a brief examination of ACEBR's Science & Wireless 2013 seminar "Health & Future RF Technologies" is an indication. In the seminar acknowledgements, the following was stated: "The ACEBR gratefully acknowledges the financial support of the National Health & Medical Research Council of Australia and Telstra Corporation, which has enabled SW2013 to run".

In Rodney Croft's introduction to the presentation by Mr. Mike Wood from the Australian Mobile Telecommunications Association (AMTA) on "4G telecommunications technologies", he said the following, in part: "Clearly what we see here is a whole lot of new technologies which are going to come about. How do we know what's going to be most relevant to us? Well, in the short term I think that our industry representatives are going to give the best indicator of this"

Croft was appointed in 2014 an Associate Editor of the BEMS journal of the Bioelectromagnetics Society (BEMS); The annual meetings of BEMS are a heavily industry sponsored event. The annual meeting celebrating the Bioelectromagnetics Society (BEMS) and the European Bioelectromagnetics Association (EBEA) was in 2015 in California (USA), had sponsors including companies such as, the Electric Power Research Institute (EPRI), Mobile Manufacturers Forum (MMF), Korean Institute of Electromagnetic Engineering Society (Mobile EMF Consortium) and, GSM-ATM5.

Croft also held talks and expert opinion on behalf of industry and for the Mobile Manufacturers Forum, a consortium of the world's major cell-phone companies. At a 5G Conference in Dubai In December 20, 2019, Croft held a lecture on behalf of ICNIRP alongside ICES Chairman Jafar Keshvari and TC95 Chairman C-K. Chou.

He joined the conference organized by the Telecommunication Regulatory Authority (TRA) of the United Arab Emirates held on December 8-9, 2019 in Dubai. Three presentations were on RF exposure safety limits: "5G RF safety concerns: New IEEE StdC95.1TM-2019" by C-K. Chou; "Scientific Basis of 5G Exposure Limits IEEE C95.1:2019 Standard" by Jafar Keshvari, and "Ensuring 5G Safety with the New ICNIRP Guidelines (100 kHz to 300 GHz)" by Rodney Croft of ICNIRP.

Croft has also actively collaborated in research with Ray McKenzie, who is a manager at the Mobile Carriers Forum (MCF) which is a special division of the Australian Mobile Telecommunications Association (AMTA) dealing with the policy, regulatory, public communications and health and safety aspects of the deployment of mobile networks in Australia.

On his website Croft's disclosure statement says: Rodney Croft has consulted to a range of organisations such as Shelharbour City Council, Department of Defence, Comcare and Optus. According to his ICNIRP declaration of interests he received personal remuneration for providing data analysis services to Heptares Therapeutics Ltd, a pharmaceutical company. And Croft received personal remuneration for providing advice to Australian Bureau of Statistics (ABS) on effects of RF devices used by field staff on field staff, resulting from a contract between University of Wollongong and ABS. He also received personal remuneration for “providing advice to Victorian Government on conducting bioelectromagnetics research, resulting from a contract between University of Wollongong and Victorian Government”.

As explained before in this report the Australian government receives billions from issuing spectrum licences to Telecom operators. In Australia, this licensing is carried out by industry regulator ACMA, the Australian Media Communications Authority. ACMA also collects a separate levy or tax from the wireless industry, money that is earmarked for scientific research on RF-EMR. ACMA then diverts $300,000 to the other government institution ARPANSA (Australian Radiation Protection & Nuclear Safety Agency) for its public information campaign) and $700,000 to the National Health & Medical Research Council (NHMRC).

According to the Australian research group ORSAA “the money that the Australian NHMRC receives in order to provide grants for medical research has mostly gone to industry-friendly researchers who have direct links with the wireless industry. For example, the largest recipient of this NHMRC research funds is Prof. Rodney Croft. He has essentially been the head of RF-EMR health research in Australia, despite his questionable qualifications for this health research role. Prof. Croft has received ample direct industry funding in addition to his lucrative NHMRC grants, which should be termed indirect industry funding.” Croft was the only Australian who played a part in determining what NHMRC research on EMR and health should be funded.

He used his international contacts at the WHO to get more Australian funding. This is how it worked behind the scenes: Croft was invited from Australia to the WHO for an expert consultation to determine which areas of medical research was needed; The Australian NHMRC research on EMR then looked to the WHO guidelines (co-influenced by Croft and ICNIRP or hi-jacked as some critics say) in order to decide their funding priorities (the 2010 WHO RF Research Agenda is the basis of funding for NHMRC research grants). Croft's laboratory then received the funding and has continued to get most of the research money over many years.

Croft had good relations with an influential industry man, Dr K. Joyner. Which researchers or research groups have been granted the NHMRC funds has been influenced to a large extent by Joyner, who was Motorola’s Director of “Global EME Strategy and Regulatory Affairs” and also represented the Australian Mobile Telecommunications Association, an industry group, on the telecommunications standards committee and the Mobile Manufacturers Forum ; Notwithstanding these ties Joyner was a longstanding member of the Standards Australia TE/7 Committee: Human Exposure to Electromagnetic Fields, and later on he was on the ARPANSA committee that set the current Australian Radiofrequency/Microwave human exposure standard. He was regarded by the cell phone companies as Australia's foremost authority on the industry's position on health issues with EMR and has represented Motorola and the Australian cell phone industry on several international standards-setting bodies. Joyner also had connections with Burson Marsteller, the PR firm representing the cell phone industry in Australia.

In October 2003 Ken Joyner, the key Motorola representative gave a presentation at the Annual Conference of the Australian Radiation Protection Society called: “A Review of RF Bioeffects Studies Relevant to the Use of Mobile Phones by Children”. Don Maisch writes in an article Motorola’s Micky Mouse Review: “The Motorola review’s conclusions as to a lack of scientific evidence of possible harm to children using mobile phones ignores a large body of expert opinion calling for a precautionary approach when it comes to children and mobile phone use.”

As reported in Microwave News (1999) in Europe there was some discontent with scientists with Motorola’s involvement with the EC research and telling European scientists how to spend research funds. As Don Maisch writes in ‘Corporate ties that bind: An Examination of Corporate Manipulation and Vested Interest in Public Health’ (2017): “In January 2009, Dr. Joyner announced that he was leaving his Director position at Motorola after 12 years and was "looking for new opportunities to work in the telecommunications industry". In that same year, Dr. Joyner was listed on the NHMRC's Peer Review Honour Roll which acknowledged its many peer reviewers and external assessors who had exhibited "excellent track records and wide-ranging expertise in Australian and international health and medical research fields". However, under the section "Administering Institution/Employer" he was listed as simply "consultant" and nothing about possible conflicts of interests. He later was appointed as the sole non-radiation expert on the 14-member Victorian government's Health department's Radiation advisory committee.

ORSAA calls this “pure corruption at a huge cost to public health everywhere. This system of funding and promoting an in-club of industry friendly researchers has kept a small number of people in powerful positions within the WHO, ICNIRP, ARPANSA etc., influencing decision making for most of the world.”

Eric van Rongen (Vice Chair ICNIRP-commission, until May 2020 chair)

Biography

Eric Van Rongen is a biologist. He is a staff member of the Dutch Health Council since 1992, where he focuses on non-ionizing radiation.

Van Rongen is a member of ICNIRP since May 2001. In 2016, he became the chair of the ICNIRP-commission. Since the beginning May 2020 he is no longer chair but vice-chair.

He also a member of the International Advisory Committee WHO EMF Project since 1995.

Van Rongen did not publish original research studies on EMF himself, only opinions or review articles.

Position

Van Rongen systematically, in scientific publications and in press articles, defends for more than twenty years the point of view that there are no dangers associated with the use of mobile phones. According to him, even for children there are no reasons to apply the precautionary principle. In 2004 for example he published an article in which he stated: 'The Health Council therefore sees no reason to recommend limiting the use of mobile phones by children.'

He systematically criticizes all studies that seem to show that non-ionizing radiation poses a problem. Recently the National Toxicologic Program (NTP) study on Cell Phone Radio Frequency concluded that there was clear evidence of tumors in the hearts of male rats But in an ICNIRP-publication Van Rongen and others stated that 'substantial limitations (of the NTP-study) preclude conclusions being drawn concerning RF EMFs and carcinogenesis.'

Possible conflicts of interest

The WHO EMF project was severely criticized in 2007 for being for a large part financed by the telecom industry, for example by the Mobile Manufacturers Forum (now Mobile & Wireless Forum), a lobby organisation of the industry.

Since 2000 Van Rongen is a member of the International Committee on Electromagnetic Safety (ICES) of the IEEE. This committee is dominated by people from industry and military. The ICES chairman Jafar Keshvari works at Intel, the chairman of one of the main committees C.K Chou at Motorola. ICES clearly is an industry lobby and standard setting organisation. Maybe Van Rongen decided for that reason to become a 'non active member' according to his declaration of personal interests 2019.

In previous years there was some competition between ICNIRP and ICES/ IEEE – at the time when the chair of ICES was still Dr. Ralf Bodemann, topshot of Siemens and Dr. B Jon Klauenberg from US Air Force Research Laboratory was the chair of ICES working group TC95. (Klauenberg was the US counterpart of former ICNIRP-chair Repacholi to lead the very start of the WHO EMF in the 90'ies.) According to an annual report of ICES it was thanks to the arrival in 2016 of Van Rongen as chair of ICNIRP that the relations with ICES improved significantly, as they were not so cordial before: "In May 2016, there was a change of leadership and some members of ICNIRP. The new ICNIRP Chairman and one of the new members of the 14-member committee are also ICES members and ICNIRP is now willing to discuss harmonization of the exposure limits found in IEEE Stds C95.1 TM -2005 and C95.6 TM -2002 and the ICNIRP Guidelines."

The ICES annual report further mentions that thanks to the invitation to do so by Van Rongen, ICES has been able to comment on the proposed new guidelines by ICNIRP. ICES workgroup TC95 formed a 19-member task group to draft a document to comment on the ICNIRP proposed guidelines on time. "ICES will maintain its collaborative relationship with ICNIRP with the goal of setting internationally harmonized safety limits for exposure to electromagnetic fields at frequencies below 300 GHz. This interaction with ICNIRP is considered a major step forward."

A year later during the annual meeting of ICES in 2017 it was stated that "ICNIRP has delayed finalizing their conclusions to give full consideration of ICES's recommendations". And Van Rongen gave a presentation saying that there is "No evidence that HF-EMF causes such diseases as cancer, no evidence that HF-EMF impairs health beyond effects that are due to established mechanisms of interaction."

Scientist Dariusz Leszczynski was a member of TC95, but resigned. He explained why on his blog: "My problem was that the membership of the IEEE-ICES-TC95 consists predominantly of the industrial scientists and the committee is chaired by C.K. Chou since the time he was employed by the Motorola. This means that all safety standards being developed by IEEE-ICES-TC95 are, in practice, developed by the industry scientists for the use by the industry they are employed by." According to Leszczynski this is a clear conflict of interests.

The latest minutes of TC95 that ICES published on its website (August 2019) show that the committee is still dominated by industry scientists.

In October 2019 Van Rongen spoke at the GSMA Europe EMF Forum. The GSM Association is a lobby organisation that defends the interests of mobile operators worldwide. In 2018, he also was a guest at the Forum. Then he defended ideas that GSMA received with pleasure: "The ICNIRP limits provide a high level of protection for all people against known adverse health effects. Dr van Rongen explained that there is no scientifically substantiated evidence that radio signals cause diseases such as cancer and that ICNIRP had considered studies such as that of the American National Toxicology Program."

In November 2019 Van Rongen presented the "ICNIRP RF guidelines revision" at 23rd GLORE (Global Coordination of Research and Health Policy on RF Electromagnetic Fields) conference held on 4th – 6rth of November in Lima, Peru. GLORE is an initiative to coordinate research and policy initiated by Japan and Korea in 1997 and joined by Europe and then by USA, Australia and Canada. Main speakers were also his ICES-colleagues Jafar Keshvari and TC95 Chairman C-K. Chou.

Van Rongen recently assured the Dutch press that there are no conflicts of interest inside ICNIRP right now. He stated: 'In the past certain members maybe received co-funding from the private sector, but currently no member has ties with the telecom sector.'

Of course, it depends on what you consider as a 'tie with industry', but his own involvement in ICES is already shows that it is not true that 'currently no member had ties with the telecom sector'. He also published articles together with researchers who did receive industry funding, for example with Bernard Veyret, who is 'a member of the Scientific Council of the French mobile operator Bouygues Telecom. His laboratory has received research funds from the same operator.' This information can be found in the footnotes of this article.

Tania Cestari

Biography

Tania Cestari received her medical degree from the University of Rio Grande do Sul and completed her medical Residency in Dermatology in Porto Alegre, Brazil and since 1995 she works as Professor of Dermatology at the same university, where she studies predominantly on clinical aspects and skin response. Dr Cestari has authored 112 scientific peer-reviewed publications, 42 book chapters and joined the ICNIRP Commission in May 2020.

Position

Dr Cestari has been doing mainly research into skin allergies and dermatological problems; We could not find any publication linked to EMF.

Possible conflicts of interest

In her 'Declaration of Interests' it is mentioned that she received research grants via the Medical Foundation of her hospital from Pfizer, Abbvie Pharmaceutical and Vichy Laboratoires for drug research.

Nigel Cridland

Biography

Nigel Cridland is Senior Group Leader at Public Health England. He joined what was to become the Public Health England (PHE) already in 1990, where he specialised in non-ionising radiation. He was member of the project team that wrote the European Commission guide to implementation of the Artificial Optical Radiation Directive (2006) and leader of the project team that developed the guide to implementation of the EMF Directive (2013).

He was Scientific Co-ordinator Mobile Telecommunications and Health Research (MTHR) Programme 2001 - 2012. Cridland was a member of the Independent Expert Group on Mobile Phones (2000). On LinkedIn he states that he was also member of the management committee of the European COST 281 action Potential Health Implications from Mobile Communications Systems.

Position

The 2000-report of the Independent Expert Group on Mobile Phones stated that 'the balance of evidence to date suggests that exposures to RF radiation below NRPB and ICNIRP guidelines do not cause adverse health effects to the general population'. But at the same time, it said: "the gaps in knowledge are sufficient to justify a precautionary approach".

The MTHR-programme (2001-2012) of which he was the Scientific Co-ordinator concluded that no association between cancer and mobile phone use was found. We can now be, said professor David Coggon, the chairman of the MTHR-programme, ‘be much more confident about the safety of modern telecommunications systems.’ Curiously enough the authors stated that: ‘We see no need for need for further research in any of the areas addressed by the research that is summarised in this report.’

Possible conflicts of interest

The MTHR-programme was funded by government and industry together, both for half of it. The final report states that to ensure that any of the funding organisation could not influence the outcome of the Programme an independent Programme Management Committee was set up. But there can be doubts about the independence of its members. From 2001 until 2007 Mike Repacholi (ICNIRP-founder, see the chapter on the history of ICNIRP) was for example member of the committee.

Guglielmo d'Inzeo

Biography

On ICNIRP’s website it reads that Guglielmo d'Inzeo is a Professor of "Bioelectromagnetic Interaction" at "La Sapienza" University of Rome since 1990. He researched active and passive microwave component design and bioelectromagnetism, mainly the interaction of electromagnetic fields with biological tissues, the effects of microwaves and ELF fields on biological samples and humans. He is author or co-author of more than seventy papers in international refereed journals and books.

He became a member of the European Bioelectromagnetics Association EBEA in 1989, and then President from 1993 to 1998. From 1992 to 2000 he was an Italian representative for the COST 244 and 244Bis projects on "Biomedical Effects of Electromagnetic Fields". From 1998 to 2004 he chaired the Italian ICEmB (Inter-University Centre Electromagnetic Fields and Biosystems). From 2001 to 2006 he was an Italian National representative in COST 281 project “Potential Health Effects from Emerging Wireless Communication Systems” and from 2007 in COST BM0704 related project.

Position

He has been active in the IEEE since the 80’ies, served as secretary–treasurer of ‘the IEEE Middle and South chapters’ and was from 2004 to 2009, also a member of the Technical Committee 95 (TC95) of IEEE International Committee on Electromagnetic Safety (ICES), of which Eric Van Rongen and Rodney Croft are also members. He published in the past 20 years a number of studies in IEEE Transactions on Biomedical Engineering and other IEEE publications, in which several times ICNIRP-founder Mike Repacholi was heartily thanked for his help.

In 2005 he was responsible for the Italian chapter of the report “European Information System on Electromagnetic Fields Exposure and Health Impacts” published on behalf of DG SANCO (European Commission), which was coordinated by the Joint research Centre (JRC of the EU); Alongside this project the “JRC developed during 2003-2004 the EIS-EMF project on behalf of DG SANCO with the overall objective of promoting cooperation among policy makers on public health and EMF risk communication issues in the EU”. What these projects basically reflect is the idea that concerns about possible health effect occur because people do not understand the issue well enough and that the concerns can be taken away by better communication.

Possible conflicts of interest

As we stated before (see Van Rongen and Croft), ICES is dominated by people from industry and military.

His declaration of personal interest 2019 is signed but only partly completed. d'Inzeo did some paid consultancy for an Italian legal office called Trifirò & Partners and for a Environmental Measurement Report Managers & Partners - Actuarial Services S.p.A in Rome. His DOI from 2016 mentions that he has been doing work for the "Marconi Foundation". The Guglielmo Marconi Foundation states to "promote research in the field of telecommunications and carries out activities devoted to the knowledge and diffusion of Guglielmo Marconi's scientific activity". The Marconi Foundation further states that "professional training and teaching play a major role" in its activities and that "their research focuses on two major fields: 1) mobile and personal communication systems, with a special focus on radio access and propagation; and 2) the computer-assisted design of non-linear microwave devices".

What is not declared in his DOI is that d'Inzeo, is a director of the scientific committee of Elettra 2000, a consortium of Marconi and other foundations. The self-declared aim of Elettra 2000 is to "spread knowledge of Bioelectromagnetics and start a dialogue between science, politics, industry and citizens, involving young people and schools." And "Elettra 2000 promotes researches and studies related to specific areas of interest. In particular, the consortium co-finances a number of national and international projects devoted to the study of the effects of electromagnetic fields on human health, in order to provide an authoritative scientific answer, fair and independent to the problem."

Elettra 2000 provides "advice to enterprises" and "owns a modern fleet of instruments for measuring electromagnetic fields in both low and high frequency" which "are available to both institutional and private entities in order to promote the improvement of standards of protection and safety of people and environment."

This paper from 2008 (The Italian national electromagnetic field monitoring network) is an example of the kind of research projects that is financing. The conclusions reads: "The monitoring campaign, combined with the travelling communication campaign contributed to create a different and more constructive approach to the problem by the citizens. This is demonstrated by the analysis of the data press that shows criticality and greater negative involvement in those areas where the monitoring campaign has been less efficient or less intense".

Furthermore, in 2019 an Italian journalist of Investigative Europe wrote the following in *Il Fatto*: "He has done multiplied scientific opinions for companies such as Vodafone, participated in European projects - all funded by industry, such as Interphone, Cosmos, Cefalo, and since the late 90s participates in the Efhran portal, where among the financiers are Deutsche Telecom and the European Association of GSM producers."

Akimasa Hirata

Biography

Akimasa Hirata is professor of Electrical and Electronic Engineering at the Nagoya Institute of Technology and Director of Center of Biomedical Physics and Information Technology.

He also is an Administrative Committee Member and Subcommittee Chairperson (SC6 EMF Dosimetry Modelling) in IEEE International Committee on Electromagnetic Safety (ICES). The latest committee (also called TC95) is the one of which Eric Van Rongen and Rodney Croft were also members.

Position

In November 2019 TC95 once again came to conclusion that the IEEE standards are safe. The authors, among which Hirata, wrote:

“a) The weight-of-evidence provides no credible indication of adverse effects caused by chronic exposures below levels specified in IEEE Std C95.1TM-2019.

b) No biophysical mechanisms have been scientifically validated that would link chronic exposures below levels specified in IEEE Std C95.1TM-2019 to adverse health effects.”

Possible conflicts of interest

As we stated before (see Van Rongen and Croft), ICES is dominated by people from industry and military.

Hirata conducted research published in *IEEE Transaction* in 2010 partly funded by KDDI Foundation. KDDI Corporation is a Japanese telecommunications operator.

But according to a recent publication Hirata himself judges that he has no conflicting interests.

Anke Huss

Biography

ICNIRP’s website states that Anke Huss is an assistant professor at the Institute for Risk Assessment Sciences (IRAS) at Utrecht University, the Netherlands. “Her research focuses on environmental and occupational exposure assessment to environmental factors including electromagnetic fields and their health”.

Huss is also involved in the GERoNiMO project, cancer and neurodegenerative diseases such as Parkinson’s disease, Alzheimer’s or ALS in the NOCCA (Nordic Occupational Cancer Study) and SNC (Swiss National Cohort) studies and on electromagnetic hypersensitivity. She is a member of the Dutch Health council, and the Scientific Council for Electromagnetic fields of the Swedish Radiation Safety Authority (SSM).

Position

She is one of the rare members of ICNIRP who seems to be aware of an industry-bias; In the book "Overpowered: The Dangers of Electromagnetic Radiation (EMF) and What You Can do about it" by Martin Blank, Anke Huss is quoted on Industry bias in research to the possible health risks of EMF.

In a scientific paper Huss writes that 82% of the research funded by public agencies or governments and 71% of the research jointly funded by industry and public sources, report health effects from RF exposure. When the research is solely funded by industry only 33% finds such a link.

Later Huss published another study in which she and colleagues examined whether the source of funding of 59 studies of the effects of low-level RF radiation has an effect on the results of studies. "Of these 59 studies, 12 (20%) were funded exclusively by the telecommunications industry, 11 (19%) were funded by public agencies or charities, 14 (24%) had mixed funding (including industry), and in 22 (37%) the source of funding was not reported." Huss et all conclude that "there is widespread concern regarding the possible health effects associated with the use of cellular phones, mobile telephone base stations, or broadcasting transmitters. Most (68%) of the studies assessed here reported biologic effects. At present, it is unclear whether these biologic effects translate into relevant health hazards. Reports from national and international bodies have recently concluded that further research efforts are needed, and dedicated research programs have been set up in the United States, Germany, Denmark, Hungary, Switzerland, and Japan. Our study indicates that the interpretation of the results from existing and future studies of the health effects of radiofrequency radiation should take sponsorship into account."

In 2010, she published a follow up study which confirmed the previous findings: "Of 75 additional studies 12% were industry-funded, 44% had public and 19% mixed funding; funding was unclear in 25%. Previous findings were confirmed: industry-sponsored studies were least likely to report results suggesting effects.

She also published in 2018 a meta-analysis based on among others epidemiologic studies "to examine associations of occupational exposure to extremely-low frequency magnetic fields (ELF-MF)" with amyotrophic lateral sclerosis (ALS).

Possible conflicts of Interests

Her DOI says she gets funding from US based EPRI for a study called TransExpo on leukaemia in children. Ironically, she states that the contract does not mention complete independence from the funder, but she explains clearly why the data will be analysed independently and "that there is no way that the funders can have an influence on what we report to them."

Ken Karipidis

Biography

Ken Karipidis has been working as a scientist at the Australian Radiation Protection and Nuclear Safety Agency (ARPANSA) since 2000. He is, states ICNIRP, 'currently the assistant director of the Assessment and Advice Section at ARPANSA where he is heavily involved in the scientific and regulatory aspects of radiation protection from electromagnetic radiation sources.'

He is member of the Scientific Expert Group since August 2015. In May 2020, he became member of the ICNIRP Commission.

Position

In 2017 Karipidis published an article with the conclusion that the exposure to radiofrequency radiation due to Wi-Fi in schools was very low. In a letter to the editor three scientists criticized the study as 'of little practical use' and 'misleading'.

Karapidis and Rodney Croft were part of a subcommittee established by ARPANSA to look at EHS and the research in 2016/17. According to an ORSAA member present in these meetings both Karipidis and Croft ignored clinical/medical evidence "in favour of poorly conducted provocation studies performed by psychologists, some of whom were funded by industry".

At the end of 2018 Karipidis together with among others Rodney Croft published a study that claimed to proof that in Australia there has been no increase in any brain tumour that can be attributed to mobile phones. That study received a lot of criticism because it excluded the group of people above sixty, which is the largest segment of the population with brain tumours.

In August 2019 Karipidis advised 40,000 Australian doctors or general practitioners via an article on the website of Royal Australian College of General Practitioners (RACGP) in which he wanted "GPs and their patients to know there is no evidence to support the concern that 5G technology, which uses radio waves and emits low-level radiofrequency (RF) electromagnetic energy (EME), will cause harms to the public". He stated: "There's been a lot of research into whether radio waves cause adverse health effects, and the only established health effects of radio waves are very high-power levels, where they raise temperature. An everyday example of that is your microwave oven at home; inside the microwave is very powerful radio waves which make the water molecules in the food bounce very fast, heating them up."

Possible conflicts of interest

In the introductory chapter, we wrote about the financial relationship between ARPANSA and the telecom industry. ARPANSA every year has a meeting with the Australian Telecommunications Association (AMTA), a lobby-organisation of the telecom industry. Minutes of this meeting made public after a Freedom of Information Request show that the funding of research was also on the agenda. 'Industry remains supportive of continued funding,' it says.

Carmela Marino

Biography

Carmela Marino studied Biological sciences in Faculty of Sciences of "La Sapienza" University of Rome. According to ICNIRP she is currently Head of the Unit of Radiation Biology and Human Health, at Casaccia Research Center of Italian Agency for New Technologies, Energy and Sustainable Economic Development (ENEA).

On behalf of ENEA she coordinated the research activity Subprogram 3 *Interaction between sources and biosystems* (MURST/ENEA-CNR Italian National Program *"Human and Environmental Protection from Electromagnetic Emissions")* and was involved in *several projects of the 5° and 6°FP, as member of steering Committee and Coordinator of research unit.*

Position

On the one hand Marino seems to agree with the official ICNIRP position; On the other hand In May 2012, during ICNIRP's 7th International NIR Workshop in Edinburgh, Marino held a lecture on the advantages, challenges and limits of experimental studies, in which she said that there is a "large number of studies but with controversial results and also a limited number of studies in relation to particular endpoints." Marino asked her fellow ICNIRP members the rhetorical question, whether these studies "really able to give conclusive information?" ICNIRP's answer to that question was and is no.

Possible conflicts of interest

Her Declaration of Personal Interests does not mention anything. Notaby, not that since April 2020 her university holds a patent based on her research, not mentioned in her DOI 2019, although the worldwide application for this patent was filed years ago.

Sharon Miller

Biography

Sharon Miller works at the Food and Drug Administration (FDA) as optical engineer since 1981. According to ICNIRP she served on numerous committees of the International Commission on Illumination (CIE) and the International Organisation for Standardization (ISO).

Position

Miller publications are mainly in the field of ultraviolet radiation and optical issues. It is difficult to find scientific publications or public statements in which she says anything about the safety of non-ionizing radiation.

Possible conflicts of interest

In her Declaration of Personal Interest Miller does not state any possible conflict of interest and we did not find any.

Gunnhild Oftedal

Biography

Gunnhild Oftedal is associate professor at the Norwegian University of Science and Technology (NTNU). According to ICNIRP she is currently, working as Research Co-ordinator at the Faculty of Information Technology and Electrical Engineering, NTNU. “From the early 1990s, she has been involved in research on health effects of EMF in the ELF and the RF ranges, mainly with experimental human studies and observational studies.

She is member of international organisations in the field of non-ionising radiation and participates in the work of WHO (Environmental Health Criteria project) on the health risk assessment on RF fields.”

She was one of the experts on a government-commissioned study, published in 2012, of possible health risks with radiation from mobile phones, base stations and wireless networks in Norway.

Position

In 2004 she answered on the questions if electromagnetic radiation from mobile phones may well affect us in other ways, too “that scientists are skating on thin ice when discussing these issues. They know little about the cause-and-effect mechanisms involved, and hence cannot eliminate the possibility that the effect of electromagnetic fields, however weak in mobile phones, may cause health problems”.

But she sticks with the official ICNIRP position and in a study for the Norwegian government she suggests that this approach is the right one: “Only effects for which there was reliable scientific evidence were used (by ICNIRP) as the basis for the exposure restrictions.”

In another recent study she concludes that “overall, the evidence points towards no effect of exposure. If physical effects exist, previous findings suggest that they must be very weak or affect only few individuals with IEI-EMF. Given the evidence that the nocebo effect or medical/mental disorders may explain the symptoms in many individuals with IEI-EMF, additional research is required to identify the various factors that may be important for developing IEI-EMF and for provoking the symptoms.”

As writes Leszczynski the ‘nocebo’ hypothesis argues that people first become aware, e.g. from news and social media, of the possible health risks of EMF-emitting devices and then worries about the possible health risk lead to develop symptoms, which they attribute to EMF exposures.

Oftedal denies in an article by IE that the health debate is polarised: ”In our field it is easy to put people in two camps, but the landscape is much more nuanced”. Also, the closed culture at ICNIRP is being denied: “People who demonstrate that they are skilled are asked to contribute.”

Possible conflicts of interest

In the study on “Mobile phone headache: a double blind, sham-controlled provocation study” co-financed by The Research Council of Norway, Norwegian Post and Telecommunication Authority, Statnett, Telenor, Norsk tele- og informasjonsbrukerforening (NORTIB), Netcom. The study found no effects.

She is member of Bioelectromagnetics society (BEMS) according to the DOI and also of the European Bioelectromagnetics Association (EBEA)

Tsutomu Okuno

Biography

Tsutomu Okuno worked for the National Institute of Occupational Safety and Health, Japan from 1980 to 2015.

He became a member of the Scientific Expert Group in 2013 and is a member of the ICNIRP Commission since 2016.

Position

Okuno was one of the authors of the ICNIRP note that criticized the NTP-study that showed carcinogenicity in rats. For the rest, his work seems mainly to be on ultraviolet radiation, not on radiofrequency radiation.

Possible conflicts of interest

In his Declaration of Personal Interest there do not seem to be sources of possible conflicts of interest and we did not find information that contradicts this.

Martin Röösli

Martin Röösli is Professor for environmental epidemiology at the Swiss Tropical- and Public Health Institute in Basel and leads the Environmental Exposures and Health Unit. His background is situated in atmospheric physics and environmental epidemiology.

In the field of non-ionizing radiation Röösli did several exposure assessments and epidemiological studies on the health effects of electromagnetic fields “including population based studies dealing with cancer, neurodegenerative diseases and non-specific symptoms of ill health”.

He is the chair of BERENIS, a Swiss expert group advising the government on electromagnetic fields and non-ionising radiation. He is a member of the advisory group of Cohort Study of Mobile Phone Use and Health (COSMOS) and between 2015 and 2018 of the the Scientific

Council of the IARC, specifically SC52. Since 2013 he is also a Member of the Editorial Board of Bioelectromagnetics.

He is still a member of the Expert Group for the Swedish Radiation Safety Authority (SSM), for which he gets 3000 Swiss francs yearly.

Relevant to this report Röösli was part of the Working Group of the IARC Monographs on the Evaluation of Carcinogenic Risks to Humans Volume 102: Non-Ionizing Radiation, Part II: Radiofrequency Electromagnetic Fields.

Position

Röösli has contributed to a study (see portrait of Anke Huss) which show that the funding of scientific research into EMF can influence the findings. Nevertheless, he confirms the general position of ICNIRP that no adverse health effects are proven.

In a study from 2010 ("Systematic review on the health effects of exposure to radiofrequency electromagnetic fields from mobile phone base stations") Röösli concludes: "Our review does not indicate an association between any health outcome and radiofrequency electromagnetic field exposure from MPBSs at levels typically encountered in people's everyday environment."

In a recent 5G report for the Swiss government Röösli et all conclude that "No health effect has been consistently proven," which he repeated in an interview.

In an annual report prepared for the Swedish Radiation Safety Authority (April 2020) by a nine-member panel of experts of which, ICNIRP vice-chair Eric Van Rongen and Röösli, which according to *MicroWave News* is published each year "as an annual update with the past year's most important scientific developments on the health effects of EMFs and RF radiation" states very bluntly that "no new established causal relationships between EMF exposure and health risks have been identified." The annual report simply does not mention the NTP report. "The two ICNIRP members and their seven colleagues made believe that the NTP report does not exist. It's not mentioned, there is no citation. Nothing at all. For the record, the NTP final report was released on November 1, 2018."

Louis Slesin of *MicroWave News* wrote: "There is a discussion of the NTP findings in last year's Swedish update. But that was based on an earlier NTP draft where the staff had opted for a weaker designation, "some evidence" of cancer. Later, after an in-depth public peer review, the NTP strengthened the conclusion to "clear evidence" of cancer. That was the headline news of 2018. "Clear evidence" was a game changer; leaving it out of the annual update is a sure sign of bias. The NTP conclusion was now qualitatively different from the earlier draft —it could well have been the title of the panel's 2018 update. But van Rongen, Röösli and the others ignored it."

On January 7, 2020 prof. Lennart Hardell and supported by 22 scientists researching EMF wrote a remarkably critical, open letter to Mrs. Simonetta Sommaruga, President of the Swiss Confederation, in which they conclude: "It is imperative that the chair and other experts evaluating scientific evidence and assessing health risks from RF radiation do not have such clear conflicts of interests or bias as Martin Röösli has. Indeed, being a member of ICNIRP and being funded by industry directly or through an industry funded foundation, constitutes clear conflicts of interest. Furthermore, it is recommended that the interpretation of results from studies of health effects of radiofrequency radiation should take sponsorship from telecom industry into account."

The group of scientists also point out to a strange contradiction in the positioning of Röösli: "Surprisingly the IARC classification from 2011 of RF-EMF exposure as class 2B, 'possibly' carcinogenic to humans, was ignored in the background material to the new ICNIRP draft on guidelines. Remarkably one of the ICNIRP commission members, Martin Röösli, was also one of the IARC experts evaluating the scientific RF carcinogenicity in May 2011. Röösli did not abstain from the IARC Group 2B classification and should be well aware of that decision, but seems now to neglect that fact being an ICNIRP member. That may be due to the fact that the IARC classification contradicts the scientific basis for the ICNIRP guidelines."

Hardell et al. suggest to the Swiss government that Mr. Martin Röösli should be released from his duties as a scientist who is not objective and has substantial conflicts of interest. On the letter Röösli reacted by saying: "It's not a scientific letter. It sounds like activists who do not use scientific facts but who just attack people. It would be much more compelling if Lennart responded to my criticism of him in a scientific way instead of derailing the debate".

A recent publication of the COSMOS (October 2019) on the outcomes states reassuringly that "using mobile phones most extensively for making or receiving calls at baseline reported weekly headaches slightly more frequently at follow-up than other users, but this finding largely disappeared after adjustment for confounders and was not related to call-time in GSM with higher RF-EMF exposure. (See also the portrait of Anissi Auvinen)

Possible conflicts of interests

Röösli does "unpaid work" for the COSMOS study, which received considerable funding from telecom companies. In the 2019-publication on this study for example, Nokia and mobile network providers TeliaSonera and Elisa are mentioned in the category 'funding'.

According to his DOI he gets 70,000 Swiss francs a year for the Berenis work, from the Federal Office for the Environment.

He also received 16,000 francs for assisting in the Working Group Mobile Phone and Radiation the Federal Office for the Environment of the Swiss government.

The Swiss Tropical and Public Health Institute in which he plays a leading role, has a lot of corporate clients of which Swisscom, the biggest telecom company in Switzerland, of which the Swiss government holds 51% of the shares. In the annual Report 2019 the institute states that of the total budget of roughly 90 million Swiss francs, 78. 6 % was "competitively acquired" and 21.4 % came from "Core contributions".

Studies selected or self-directed by Röösli, were directly funded by the (Research Foundation for Electricity and Mobile Communication)

of which Martin Röösli is a member since 2011, according to his CV on the website of the Swiss Tropical and Public Health Institute. FSM is "a non-profit-making foundation with the purpose of promoting scientific research into the chances and risks of radio and electric power technologies that produce and use electromagnetic fields". The five founders of the FSM are:

ETH Zurich, Swisscom, Salt, Sunrise, 3G Mobile (liquidated in 2011) and the current main sponsors are Swisscom and Swissgrid. The sponsors are also represented in the FSM Foundation Board with one delegate out of seven.

Soichi Watanabe

Biography

Watanabe is currently Director of the Electromagnetic Compatibility Laboratory of the "National Institute of Information and Communications Technology (NICT).

He was a member of ICNIRP Standing Committee III since 2004 and is a member of the Commission since 2012.

He is a guest lecturer of several universities and at the Central Research Institute of Electric Power Industry.

Position

All publications to which Watanabe contributed as author point in the same direction: no effect. For example, this article about tumorgenenis in rats.

In 2019, he was co-author of an article which stated: 'To date, no adverse health effects of the EMF, linked to these applications, have been established.'

Possible conflicts of interest

As a guest lecturer at the Central Research Institute of Electric Power Industry he receives a small amount (about € 450 for each lecture, 1 or 2 a year).

He was co-author of the article with commission-member Hirata on the research funded partly by KDDI Foundation.

MEMBERS WHO HAVE LEFT THE ICNIRP COMMISSION IN MAY 2020

Maria Feychting

Biography

Maria Feychting is a Professor of Epidemiology at the Institute of Environmental Medicine, Karolinska Institutet, Stockholm, Sweden.

She joined the Commission in 2008 and was elected vice chair in 2012. She left the Commission in May 2020.

Position

Feychting was in charge of the Swedish part of the Interphone study which concluded that there was no link between brain tumours and mobile phone use.

Feychting also conducted the Swedish part of the COSMOS-study, which in 2011 came to the conclusion that there was no increase in glioma in the Nordic countries that could be attributed to the use of mobile phones.

She recently repeated this point of view in the media in an article on the risks of 5G, which were none according to her.

According to this source she criticized the NTP-study on false grounds.

Possible conflicts of interest.

In a 2019 study in the context of COSMOS, she declared a declaration of interest as "vice chairman of the ICNIRP".

The telecom industry contributed € 5.5 billion to the funding (total € 19.2 billion) of the Interphone Study.

A 2016 publication on the Interphone Study once again mentioned industry funding by among other the Mobile Manufacturers Forum.

The Swedish part of the COSMOS-study was partly funded by the telecom industry: TeliaSonera, Telenor and Ericsson. In her Declaration of Interests for 2015 she declares that her Institute received a grant from industry sources which constituted "no more than 4% of her unit of epidemiology total income."

A 2011 study was partly funded by the Swiss Research Foundation on Mobile Communication, an organisation which is founded and funded by the telecom industry.

A 2012 study was funded by the Electric Power Research Institute (EPRI), an organisation funded by industry.

She did not mention these sources of funding in her Declarations of Personal Interest.

Adèle Green

Biography

Green is an Australian epidemiological scientist at the Queensland Institute of Medical Research, Australia and is the institute's Head of Cancer and Population Studies Group. She specialised in UV and skin cancer causation, harmful effects of UVR exposure in childhood and the prevention of melanoma. Apart from various Australian research bodies, she was also member of many committees at the International Agency for Research on Cancer (IARC) and contributed to the IARC monograph that led to classification in

Position

Although she focussed mostly on UV radiation, Green seemed to agree with her ICNIRP colleagues on the ICNIRP position, for example in this study from 2005 where Green was first author the research did not find any consistent or biologically relevant effect of specific radiation on cells. And another study from 2009 Epidemiologic Evidence on Mobile Phones and Tumor Risk, concludes by saying that “In the last few years, the epidemiologic evidence on mobile phone use and risk of brain and other tumors of the head has grown considerably. In our opinion, overall the studies published to date do not demonstrate a raised risk within approximately 10 years of use for any tumor of the brain or any other head tumor.” And despite certain methodologic shortcomings and limited data on long-term use, “the available data do not suggest a causal association between mobile phone use and fast-growing tumors such as malignant glioma in adults, at least those tumors with short induction periods.”

Conflicts of Interests

The declarations of interests of Dr Green have disappeared from the ICNIRP’s website. The IARC Monograph mentions that Dr Green received “research funds (not exceeding 5% of total research support) from L’Oréal which makes products intended to reduce the dose from solar radiation.”

Zenon Sienkiewicz

Biography

Sienkiewicz worked until his retirement in 2018 for Public Health England. There he led a research group that investigates the effects of ionizing and non-ionizing radiation. Since 2011 he has been a member of ICNIRP. He was also external expert for the Scientific Committee on Emerging and Newly Identified Health Risks (SCENIHR) report on ‘Potential health effects of exposure to electromagnetic fields (EMF)’, adopted in January 2015.

Position

Sienkiewicz systematically defends the position that there is no proof for any harm caused by non-ionizing radiation. In 2002, he said in the media: "The bottom line is there are no known mechanisms by which mobile phone radiation can increase the risk of cancer." Fifteen years later he still holds exactly the same position. In a 2017-article he stated that all the extensive research done has ‘not identified any public health risks with any degree of certainty.’ Moreover, it concluded that ‘animal studies investigating the carcinogenic potential of exposure to multiple RF frequencies should not be given a high priority for research at this time.’

Possible conflicts of interest

A remarkable fact in his latest Declaration of Personal Interests is that he has shares in telecommunications multinational BT Group, one of the largest telecommunications companies in the world from 2003 to the present day. The gain is very little: about 100 pounds a year. But still: if you want to avoid the impression of conflicts of interest buying shares in a telecom company doesn't seem to be a wise decision.

He himself acknowledges this is a potential conflict of interest. Under an article published in 2017 the 'Statement on the Conflict of Interest' is: The authors declare that this work was conducted in the absence of any commercial or financial relationships that could be constructed as a potential conflict of interest, *except Sienkiewicz declares that he has owned 440 ordinary shares in BT Group, a communication services company.*'

In his 2015 Declarations of Interests he declares to have done since 2012 "Provision of research and scientific advice to UK government and other stakeholders". It is not specified who those other stakeholders were, but it can be assumed those were not civil society groups.

Also since 2009, he has been a consultant to the Rapid Response Group at the Japan EMF Information Center, which is funded by "Japan Electrical Safety & Environment Technology Laboratories, where he conducts reviews and analyses of recently published scientific studies

He was between 2001 and 2012 member of the Mobile Telecommunications Health Research (MTHR)-programme. The programme did not find any association between exposure to mobile telephone communication and an increased risk of developing cancer. In the final report of the programme we read that that the core funding was provided in approximately equal share by government and industry. He systematically defends the point of view that there are no health risks associated with non-ionizing radiation. He was co-author of the 2019 article which criticized the NTP-study.

SCIENTIFIC EXPERT GROUP

Jacques Abramowicz

Biography

Jacques Abramowicz is Professor of Obstetrics and Gynecology and the Director of the Ultrasound Services at the University of Chicago.

He is a member of the Scientific Expert Group since May 2016.

Position

Abramowicz is, says his personal page at Chicago University, "an expert in the use of ultrasound for prenatal diagnosis of foetal anomalies and screening for early detection of ovarian cancer."

As far as we could find out, he did not perform research into the health effects of mobile phone radiation.

Possible Conflicts of Interest

In his declaration of personal interests Abramowicz doesn't mention possible conflicts of interest and we did not find information that contradicts this.

Anssi Auvinen

Biography

Auvinen is currently a professor of Epidemiology at the School of Health Sciences, University of Tampere in Finland. He is a member of ICNIRP's Scientific Expert Group since 2013. He was also external expert for the Scientific Committee on Emerging and Newly Identified Health Risks (SCENIHR) report on 'Potential health effects of exposure to electromagnetic fields (EMF)', adopted in January 2015.

Position

In harmony with all ICNIRP-members Auvinen criticizes research that seems to show an association between health problems and mobile phone use. Although there have been individual reports of associations between MP-use and tumours, this research is not consistent and on balance does not provide evidence of an association,' he and his co-authors wrote in 2008. His own research systematically shows no association between health problems and non-ionizing radiation.

Auvinen participated in the Finish Cohort Study of Mobile Phone Use and Health (COSMOS). A recent publication (October 2019) on the outcomes states reassuringly that "using mobile phones most extensively for making or receiving calls at baseline reported weekly headaches slightly more frequently at follow-up than other users, but this finding largely disappeared after adjustment for confounders and was not related to call-time in GSM with higher RF-EMF exposure. Tinnitus and hearing loss were not associated with amount of call-time." In another publication on the COSMOS-outcomes (April 2020) an association between sleep quality and mobile phone use is also not found.

Possible conflicts of interest

In his Declaration of Interests he submitted to ICNIRP he states that he in 2014 and 2015 received research € 100,000 funding from the Mobile Manufacturers Forum, an international organization founded in 1998 by leading manufacturers of mobile phones and radio equipment, such as Alcatel, Ericsson, Mitsubishi Electric, Motorola, Nokia, Panasonic, Philips, Sagem, Samsung, Siemens and Sony Ericsson.

The funding was for the COSMOS-study. In the 2019-publication on this study Nokia and mobile network providers TeliaSonera and Elisa are mentioned in the category 'funding'.

Another recent article states that Auvinen received 'consulting fees from Epid Research Inc.' According to his Declaration of Interest he received a fee of € 1000 in 2015 and 2017. Not in his declaration of interest is that he received lecture fees from pharmaceutical companies Glaxo Smith Kline and MSD. Maybe one can argue that these companies do not operate in the field of non-ionizing radiation. But to avoid conflicts of interests it seems wise to be transparent about all fees and funding received from industry.

Christian Cajochen

Biography

ICNIRP's website states that Cajochen studied natural sciences followed by a 3-y postdoctoral stay at the Harvard Medical School in Boston, USA. He leads the Centre for Chronobiology at the University of Basel and focusses on the influence of light on human cognition, circadian rhythms and sleep, circadian related disturbances in psychiatric disorders, and age-related changes in the circadian regulation of sleep and neurobehavioral performance.

He serves as associate editor for established sleep-related scientific journals and is editor in chief for “Clocks&Sleep”.

He started as a member of the Scientific Expert Group (SEG) in May 2018.

Position

As stated Cajochen focusses on the influence of lights and far as we could find out, he did not perform research into the health effects of mobile phone radiation.

Possible conflicts of interest

In his DOI it is stated that he studies the “effects of day LED on human performance, melatonin and sleep. Research studies in healthy human volunteers partially sponsored by Toshiba Materials.” In the period from 2014-2018 that accounts for 120.000 (we assume euro), whereby Toshiba has the right “to request (i) revisions to the publication, so that no Confidential Information is inadvertently disclosed or a delay of not more than 60 days to allow for protection of any potentially patentable subject matter by filing of a patent application.”

Toshiba does not focus on telecommunications, but rather on mainly infrastructure energy and Electronic Devices.

Jose Gomez-Tames

Biography

Gomez-Tames is Research Associate Professor in Nagoya Institute of Technology.

He is also Working Group Chair of the Subcommittee on EMF Dosimetry Modelling of the IEEE International Committee on Electromagnetic Safety from 2017.

Gomez-Tames is member of the Scientific Expert Group since 2018.

Position

Gomez-Tames work is more on the modelling of non-ionizing radiation than on the health effects.

Possible conflicts of interest

See Van Rongen and others on the role of IEEE/ICES.

In his Declaration of Personal Interest Gomez-Tames doesn't mention other sources of possible conflicts of interest and we did not find information that contradicts this.

Penny Gowland

Penny Gowland worked at the University of Nottingham School of Physics and Astronomy until 2016 and is now retired. She did a PhD in Magnetic Resonance Imaging from the Institute of Cancer Research in 1990.

According to ICNIRP's website "her work at high field and on foetal development as led her to take a strong interest in the interactions of EMF with the human body, and safety aspects of MRI."

Penny Gowland is a member of the ICNIRP Scientific Expert Group (SEG) since March 2013.

Position

She declared in her DOI that her "research interests are in MRI: but I am also academically and professionally interested in any biological effects of EMFs."

As stated Gowland focussed mainly on MRI and far as we could find out, she did not perform research into the health effects of mobile phone radiation.

Possible conflicts of interest

According to the organisation AVAATE her previous Declaration of Interests, she reported that she has held many research contracts with Phillips Electronics but without any money involved. Gowland has been part of the MR safety working group of British Institute of Radiology. According to the British Institute of Radiology website, Phillips and Siemens are platinum sponsors.

In 2015 AVAATE also stated that the European Society for Magnetic Resonance in Medicine and Biology (ESMRMB), organization mentions that Gowland was a member of several committees, including the Committee on Security, and has received financial support from companies like Hitachi, Philips, Siemens, Toshiba and General Electric.

John Hanifin

Biography

John Hanifin is laboratory director of the Light Research Program at Thomas Jefferson University.

He is a member of the Scientific Expert Group since May 2018.

Position

Hanifin is specialized in the effects of light. A recent publication he contributed to is for example is about the effect on nurse and patient experience of the overnight use of blue depleted illumination. He did not conduct research on the health effects of mobile communications technologies.

Possible conflicts of interest

The Light Research Program received industry support from among others OSRAM, Philips Lighting and Panasonic.

His PhD-thesis (2015) was also party funded by industry, by Philips Lighting, Apollo Lighting and OSRAM.

Hanifin's Declaration of Personal Interest shows that his laboratory earns about 5% of its yearly income by conducting clinical research for Bios Lighting. It mentions that his laboratory is obliged to submit a manuscript to the sponsor before publication for review and comment, 'however Sponsor shall not exercise editorial control over the publication'. The fact that the sponsor can review and comment the manuscript does not seem to be a strong guarantee of independence.

Jukka Juutilainen

Biography

He is a retired professor emeritus of Radiation Biology and Radiation Epidemiology, and Department Head of the Department of Environmental Science at the University of Eastern Finland. Juutilainen teaches generic courses on environmental health and risk assessment, as well as specific courses on non-ionizing and ionizing radiation

He is an Associate Editor of *Bioelectromagnetics*, effective immediately for which he was nominated by the European Bioelectromagnetics Association (EBEA) a non-profit scientific association with many current and former ICNIRP-members.

He was a member of the ICNIRP Standing Committee on Biology from 2004 until 2012 and became a member of the Scientific Expert Group (SEG) in March 2013.

Position

In 2007, *Microwave News* reported positively about a study published by Juutilainen: “Every now and then a new paper comes along that gives hope that one day we'll make sense of the conflicting results that have become the hallmark of EMF research.” The study was financed partly by the cell phone industry —the MMF and the GSMA and although Juutilainen suggested that needed a follow-up it never got one.

Another study from 2007 concluded that “the data did not show any effects of radiofrequency electromagnetic fields on micronucleus frequency in erythrocytes. The findings were consistent in two mouse strains (and in a transgenic variant of the second strain), after 52 or 78 weeks of irradiation, at three SAR levels relevant to human exposure from mobile phones, and for three different mobile phone signals.” The study was co-funded by Nokia, Elisa Communications Corporation, Finland Benefon, Finland Sonera.

Juutilainen published this study in 2009, together with Croft and Van Rongen, on the ‘Effects of Radiofrequency Electromagnetic Fields on the Human Nervous System’. The conclusion was that “However, in provocation studies a causal relation between EMF exposure and symptoms has never been demonstrated. There are clear indications, however, that psychological factors such as the conscious expectation of effect may play an important role in this condition.”

Possible conflicts of interest

In his past ICNIRP Declaration of Interests, he stated that he has received research funding from government organizations and foundations.

In his last non-signed DOI he indicates “The Department of Environmental and Biological Sciences of the University of Eastern Finland (UEF) has received funding from the Electric Power Research Institute (EPRI). Although EPRI is an independent, non-profit research organization (and therefore not reported above in research support received from commercial entities), this funding might be perceived as affecting my independence (Period: 2015-2019).”

According to AVAATE he had “numerous research programs funded by Nokia, Benefon, Sonera, Elisa, FINNET, the GSM Association and the Mobile Manufacturer Forum.” For example, the national research programme on possible health effects of mobile phones in Finland (from 1998 to 2003) which was coordinated by Juutilainen was mainly funded by TEKES, National Technology Agency a governmental organisation, and also supported by Nokia, Benefon, Sonera, Elisa, Radiolinja, Finnish 2G, Mobile Manufacturers Forum and the GSM Association.

He has participated in conferences and publications funded in part by organizations with interests in the telecommunications sector.

Masami Kojima

Biography

Masami Kojima is a professor of Kanazawa Medical University. He is specialized in ocular damage due to microwaves.

In the period 2001-2004 he was a consulting member for ICNIRP, since november 2014 he is a member of the Scientific Expert Group.

Position

Kojima's research is mainly on the effects of microwaves on the eye, often of rabbits. In his publications, we found no direct statements about possible effects on the eye within the ICNIRP-norms.

Possible conflicts of interest

He was co-author of the 2010 article partly funded by KDDI Foundation (see Hirata and Watanabe).

His Declaration of Personal Interest does not mention other sources of possible conflicts of interest and we did not find any.

Ilkka Laakso

Biography

He is Professor of Electromagnetics in Health Technologies at Aalto University, Finland and focuses on theoretical and computational bioelectromagnetics at both extremely low and radio frequencies. Laakso has been "combining computational electromagnetics with medical image processing and biological neuron modelling." The purpose of this research is to offer the medical and electrical engineering community new computational methods for individual physical modelling of the human body.

According to ICNIRP's website he is the "secretary of Subcommittee of EMF Dosimetry Modeling (SC6) of the IEEE International Committee on Electromagnetic Safety and a working group chairman since 2015."

Laakso became a member of the Scientific Expert Group (SEG) in 2016.

Position

A study from 2009 (Assessment of the Computational Uncertainty of Temperature Rise and SAR in the Eyes and Brain Under Far-Field Exposure From 1 to 10 GHz') about the specific absorption rate (SAR) seems to suggest that the 'reference levels by ICNIRP and maximum permissible exposure limits by IEEE seemed to be conservative in the sense that at the reference levels the temperature rise in the eyes and brain was always less than 1◦C."

Possible conflicts of interest

For IEEE/ICES see Van Rongen and others.

According to his DOI for ICNIRP he owns stocks of and is a board member of 'Fieldsim Oy', a consulting company in Finland that does computer simulations of electromagnetic fields, including electromagnetic field exposure.

Isabelle Lagroye

Biography

Isabelle Lagroye is a director of studies at the Ecole Pratique des Hautes Etudes (EPHE) and works at Bordeaux University. Her research, states a recent publication, 'deals mainly with the biological and toxicological effects of non-invasive electromagnetic fields.' She is currently member of the Bruxelles-Capitale expert committee on non-ionising radiations.

She was member of an ICNIRP committee in the period 2009-2012 and was elected member of the Scientific Expert Group in March 2013.

Position

In 2018 Lagroye together with two other scientists published an article in *European Scientist* in which she concluded that the NTP-study "consolidates current knowledge and reinforces the fact that when effects of mobile radiofrequency fields can be observed, it is at exposure levels that far exceeds the maximum permissible exposure values. In practice, these limits cannot be reached with commonly used wireless communication technologies (relay antennas, mobile phones, Wi-Fi …)."

This statement seems to be in contradiction with findings from her own research. A recent publication of which Lagroye was co-author concludes: 'However, we found that exposure to GSM-modulated 1800 MHz signals at 2 W/kg decreased the PMA maximal efficacy to activate both RAS and ERK kinases' activity.' So, it influences the signaling between proteins.

This is an effect at 2 W/kg, while according to the new ICNIRP-norms health effects in head and torso are only above 20W/kg and the norm is, with a safety factor of ten, 2W/kg.

Lagroye was also co-author of the final report of the Geronimo-project. In this report, we do find indications for health effects. It says:

"Results suggest that increased RF dose to the brain and longer mobile phone call time may be associated with risk of hyperactivity and conduct problems."

And: "a meta-analysis among four birth cohorts (n=55,507) indicated that maternal cell phone use during pregnancy may be associated with shorter pregnancy duration and increased risk for preterm birth (Tsarna et al., 2019, accepted Am J Epidemiol)."

Interesting is also that research conducted by Lagroye seems to suggest non-thermal effects, while ICNIRP states that thermal effects are the only ones for which there is scientific evidence. In this article the authors write: "Altogether, our experimental findings provide evidence for dose-dependent effects of RF signals on the bursting rate of neuronal cultures and suggest that part of the mechanism is non-thermal."

In 2009, she co-authored a scientific paper with Van Rongen and Croft which stated on the 'effects of radiofrequency electromagnetic fields on the human nervous system' that "there are clear indications, however, that psychological factors such as the conscious expectation of effect may play an important role in this condition."

Possible conflicts of interest

The latest Declaration of Personal Interest of Lagroye that can be found on the ICNIRP-site dates from 19 October 2015, almost five years ago. At that moment, she stated that she got 2,35% of the income of her research unit from a commercial partner, the Réseau de Transport d'Électricité (RTE).

A study published in 2010 which suggested that exposure to WiFi did not damage the brains of young rats was funded by France Telecom and La Fondation Santé et Radiofréquences, an organisation that is for the half funded by industry.

This organisation also partly funded several other studies to which she contributed, like this one published in 2011 and this one published in 2012.

Another 2012 publication was partly funded by Bouygues Telecom.

Sarah Loughran

Biography

ICNIRP's website states that Loughran is currently a researcher at the University of Wollongong in the Australian Centre for Electromagnetic Bioeffects Research (ACEBR) human neurophysiology research group, an NHMRC Centre of Research. She studied physiology and psychology and got a PhD in cognitive neuroscience/psychophysiology at Swinburne University of Technology, investigating the effects of electromagnetic fields on human sleep, the electroencephalogram (EEG), and melatonin.

To this centre (ACEBR) also ICNIRP-chair Rodney Croft and ICNIRP-member Andrew Wood are connected. Swinburne university and in particular the Radiofrequency Dosimetry Laboratory is part of the ACEBR which has a very close relationship with and is co-funded by Telstra, the biggest Telecom company in Australia. (See also portraits on Woods and Croft)

Loughran is also a member of the current World Health Organisation (WHO) RF Environmental Health Criterion evaluation committee, and is on the board of directors for the Bioelectromagnetics Society (BEMS). She is a member of the ICNIRP Scientific Expert Group (SEG) since March 2013.

Position

A 2005 study by Loughran and Woods on the effects of EMF on human sleep demonstrated that "a short exposure to mobile phone-type radiation has an effect on subsequent sleep EEG, although no conclusions can be made regarding adverse health consequences as the mechanisms of the effects are still unknown."

In 2007 Microwave News reports that "the ability of mobile phone radiation to affect sleep is emerging as a robust low-level effect. A team led by Bengt Arnetz has reported that a three-hour exposure to GSM radiation at 1.4W/Kg an hour before bed can disrupt sleep." This study supported earlier findings of Peter Achermann of the University of Zurich and Loughran at the time working at the Brain Sciences Institute at Swinburne University.

Because later findings of other studies got quite some media attention, Loughran, Peter Achermann & Niels Kuster published a statement to temper the seriousness of the findings.

Loughran worked for some years in Switzerland, where several scientists like Kuster do research on EMF and sleep. *The Nation* reported that Niels Kuster, a Swiss engineer co-authored in *The Lancet Oncology* a summary of the WHO's findings of the Interphone study which was launched by the WHO's International Agency for Cancer Research in 2000 (and to which two wireless trade associations contributed $4.7 million or 20 percent of the $24 million budget). Kuster had filed a conflict-of-interest statement affirming that his research group had taken money from "various governments, scientific institutions and corporations." But after his publication The Lancet "issued a correction expanding on Kuster's conflict-of-interest statement, noting payments from the Mobile Manufacturers Forum, Motorola, Ericsson, Nokia, Samsung, Sony, GSMA, and Deutsche Telekom. Nevertheless, Kuster participated in the entire 10 days of WHO-deliberations."

In general, Loughran (ACEBR) is in agreement with Croft. In an interview with Computerworld: "*There are people that are suffering and yes, it's **not due** to electromagnetic energy exposure, it's more of a **psychosomatic** condition*…"

According to a 2017 study "IEI-EMF provocation case studies: A novel approach to testing sensitive individuals" of which Loughran is the second author "*the present experiment failed to show a relationship between RF-EMF exposure and an IEI-EMF individual's symptoms*". The information on Electro hypersensitivity from the WHO's EMF Project (see also History chapter in this report) to which Loughran is connected has not been updated since 2005.

Possible conflicts of interest

In her DOI she declares for 2015 having received almost 16.000$ from EPRI funding a*nd NPF research Institute, which accounted "approximately for 5% of her lab's income".*

In a 2016 EPRI workshop "Loughran provided an overview of the current state of knowledge in the field of human laboratory studies, an assessment of the critical gaps in knowledge, and recommendations for research priorities. Loughran and the session rapporteur, Rodney Croft, University of Wollongong, led the workshop participants in a discussion of human laboratory studies".

See also portraits on Croft and Wood.

Jack Lund

Biography

Jack Lund was research physicist with the US Army Medical Research Command. There he studied the effect of laser radiation on ocular tissue and the visual system. He retired in 2018.

He was an ICNIRP Consulting Expert from 2002 to 2012. He joined the Scientific Expert Group in 2018.

Position

Jack Lund is an expert in laser safety issues. He did not publish article about the health effects of mobile communication technologies and did not make, as far as we could find out, make public statements about it.

Possible conflicts of interest

Lunds '[Declaration of personal interest]' is completely empty. We did not find other information about possible conflicts of interest.

Simon Mann

Biography

According ICNIRP's website Simon Mann is a chartered electrical engineer and heads the Physical Dosimetry Department at Public Health England's Centre for Radiation, Chemical and Environmental Hazards. Man is responsible for programmes of scientific work to develop health-related advice on exposures to electromagnetic fields (EMFs) and optical radiation across the UK.

He was secretary to the independent Advisory Group on Non-ionising Radiation (AGNIR), and member of the IARC Working Group that evaluated the carcinogenic potential of radiofrequency EMFs in 2011. He currently works with WHO EMF Project (see also history part) to develop its Environmental Health Criteria monograph on radiofrequency fields.

He is also active in technical standardisation and is a UK delegate to the CENELEC TC106X Committee.

During [a meeting of the WHO EMF Project] in 2013 Lindsay Martin from ARPANSA – (Australia) and Simon Mann (PHE - UK) were elected chair and vice chair respectively. In the meeting J. Keshvari from International Committee on Electromagnetic Safety (ICES)and the International Electrotechnical Commission (IEC) TC 106 said that "Maintenance work is in hand on several EMF exposure Standards. Harmonisation and avoiding duplication of effort, between CENELEC, IEEE and ITU is encouraged where possible." Keshvari also mentioned that IEEE/ICES "has been developing an RF safety Standard for NATO".

He is a member of the ICNIRP Scientific Expert Group since 2015.

Position

Mann is part of the close network of ICNIRP and WHO EMF scientists that claim there are no real immediate health effects from EMF. For more on the WHO Project and EMF IEEE/ICES, see the history part of this report and the portrait of Croft and Van Rongen.

Possible conflicts of interest

We could not find a recent DOI on ICNIRP's website: the link to Mann's DOI on ICNIRP's website is not functioning.

However, he did not mention in his former Declaration of Interests statement submitted to ICNIRP, that he has received research funding from the GSM association, the Mobile Manufacturer Forum and the UK's Mobile Telecommunication and Health Research Program (MTHR), on which he still plays a leading role. According to AVAATE MTHR in the past received funding from the Vodafone, a wireless company.

Since 2009 he has been a member of BEMS and the EBEA22.

Rüdiger Matthes

Biography

Rüdiger Matthes was from 1989 until his retirement in 2016 Head of the group "Non-Ionizing Radiation (Dosimetry)" at the German Federal Office for Radiation Protection. He became the Scientific Secretary of ICNIRP in 1993. He was Chairman of the Standing Committee on Physics and Engineering (SCIII) from 2004 to 2008. He became Vice-Chair in 2008, and Chair again in 2012. Since 2016 he is a member of the Scientific Expert Group.

Position

Matthes defends the position that there are no studies that prove the existence of non-thermal health effects of non-ionizing radiation and that no plausible mechanism has been described whereby these effects could take place. There is no evidence for a link between cancer and the use of mobile phones, he said in 2010.

Matthes was one of the authors of a recent ICNIRP-publication in which ICNIRP explains the principles for health protection on which its guidelines are based.

Possible conflicts of interest

In his Declaration of Personal Interests Matthes does not mention any possible conflict of interest and we did not find any information that contradicts this.

During a meeting of the WHO EMF Project in 2013 Matthes spoke on behalf of both BfS and ICNIRP by stating that: “Exposure recommendations have been developed by several organisations such as ICNIRP and IEEE/ICES, and there is good harmonisation between these on fundamental limits.”

John *O'Hagan*

Biography

On ICNIRP’s website it says that John O’Hagan heads the Laser and Optical Radiation Dosimetry Group at Public Health England. This research group covers all aspects of optical radiation dosimetry, including both the beneficial and detrimental effects of optical radiation on people.

He is Vice-President Standard of the International Commission on Illumination (CIE), Convenor of the International Electrotechnical Commission Technical Committee 76 “Optical Radiation Safety and Laser Equipment” Working Group 9 “Non-coherent sources”, Chairman of the British Standards Committee EPL/76 “Optical Radiation Safety and Laser Equipment” and is a member of a number of other national and international committees.

According to his DOI he was also a member of EU SCENHIR/SCHEER Working Group on Potential risks to human health of Light Emitting Diodes (2016-2018) and is a Member of WHO Core Group on NIR Basic Safety Recommendations.

He joined the ICNIRP Scientific Expert Group (SEG) in March 2013.

Position

In 2017 O’Hagan co-wrote a chapter in Clay's Handbook of Environmental Health in which the general line of ICNIRP, SCENHIR and WHO EMF Project is repeated: no adverse health effects.

Possible conflicts of interest

In his DOI he states under activities “Provision of scientific support and advice to government and other stakeholders”, but fails to mention which stakeholders.

In his statement, he says that he is the President of the Committee EPL/76 Optical radiation safety and laser equipment, of BSI Standards Development (BSI is a company that sets rules to help organizations worldwide achieve excellence). Organizations that work with this committee include the Association of Industrial Laser Users, the Association of Manufacturers of Domestic Appliances, GAMBICA Association Limited (a UK national organisation representing the interests of companies in the instrumentation, control, automation and laboratory technology industry) the Institute of Physics, the Institution of Engineering and Technology, the Institution of Mechanical Engineers, and the Lighting Industry Association.

He also reports that he is the Vice President of the CIE-UK National Illumination Committee of Great Britain. This committee was established by the Illuminating Engineering Society of

Great Britain, the Institute of Electronic and Electrical Engineers, the Institute of Gas Engineers, and the NPL, in collaboration with industry and professional associations, government departments and lighting technicians.

Chiyoji Ohkubo

Biography

Chiyoji Ohkubo is Director of the Japan EMF Information Center (JEIC). This organisation was established in July 2008 'to facilitate communication on EMF issues among government agencies, industry, the media and the general public.'

In the period 2005-2007 he worked for the EMF WHO-project.

He is a member of Scientific Expert Group since March 2013.

Position

All his publications seem to fit into the same category: no effect. See for example this study in which the exposure of rats to RF EMF radiation did not alter their cerebral microcirculation.

Possible conflicts of interest

For criticism of the WHO EMF Project see among others Van Rongen.

The Japan EMF Information Center, writes Okhubo himself, 'has been financed from donations by stakeholders and governmental funds.' An information leaflet of the organisation says: 'The JEIC is founded to present in a neutral way the positions of industry, science and society, and to discuss the risk analysis.' It seems to be no coincidence that industry is mentioned first.

Ohkubo did research funded by the Association of Radio Industries and Businesses (ARIB), Japan.

Margarethus Paulides

Biography

Margarethus ('Maarten') Paulides obtained his MSc in Electrical Engineering at Eindhoven University in 2002 and his PhD in Medical Electromagnetics

He works as Associate Professor, Department of Electrical Engineering, Electromagnetics, at the university of Eindhoven as well as Associate Professor, Erasmus Medical Centre in Rotterdam.

The outcome of his research were novel devices, patient-specific simulation technology and pioneering data and knowledge for improving EMF exposure guidelines.

Since 2015 he is board member of the Dutch National Antenna Research Framework (NARF). From 2017, he serves in the Electromagnetics Committee of the Dutch Health Council that advises the relevant ministers in the Netherlands on EMF related subjects. He also is a Management Committee member and Workgroup leader in COST action CA17115.

He is a Member of the ICNIRP Scientific Expert Group (SEG) since 2017.

Position

Most of his research is focussed on applications in health monitoring, disease diagnosis and therapy. We did not find much research on the health effects of radiofrequency radiation.

He did some research on thermal effects on tissue which resulted in this 2018 study in which the authors basically state that the protection levels of ICNIRP and IEEE are conservative and safe: “To protect against any potential adverse effects to human health from localised exposure to radio frequency (100 kHz-3 GHz) electromagnetic fields (RF EMF), international health organisations have defined basic restrictions on specific absorption rate (SAR) in tissues. These exposure restrictions incorporate safety factors which are generally conservative so that exposures that exceed the basic restrictions are not necessarily harmful.”

Possible conflicts of interest

According to the ICNIRP website he “also acts as advisor of start-up companies aimed at providing solutions for computer simulation and image guided interventions”.

His DOI further states that he does paid consultancy for a company Sensius.biz, which in fact he co-founded, for an amount of 5000€. He also owns 4,9% in stocks of this company.

The same amount he got from a German company Sennewald Medizin Technic.

He received a 45.000€ research Grant form General Electric Research Centre in Germany.

For the contracting company Phillips he received a STW research grant of 10.000€ in cash and 66.300€ in kind.

Kensuke Sasaki

Biography

Kensuke Sasaki is a Researcher of the National Institute of Information and Communications Technology, Japan.

He is a member of Subcommittee of EMF Dosimetry Modelling of IEEE International Committee on Electromagnetic Safety. He is also an expert for a committee of the International Electrotechnical Commission.

He joined the Scientific Expert Group in November 2018.

Position

Most publications of Sasaki are about how to measure the effects of non-ionizing radiation and about the thermal effects of it on for example the eye. We did not find direct statements about the health effects.

Possible conflicts of interest

For information about IEEE/ICES see Van Rongen.

Together with Hirata and Watanabe (see above) he conducted research published in *IEEE Transaction* in 2010 partly funded by KDDI Foundation.

David Savitz

Biography

Savitz is currently Professor of Epidemiology and Obstetrics and Gynecology, at the American Brown University.

His teachings and research is focussed mainly on epidemiologic methods and, reproductive, environmental, and cancer epidemiology and he authored a book entitled “Interpreting Epidemiologic Evidence”.

He was a member of the ICNIRP Standing Committee on Epidemiology from 1997 until 2012 and then became a member of the ICNIRP Scientific Expert Group (SEG) in 2013.

Position

Given the fact that he has been connected to ICNIRP for 23 years we can safely assume that he agrees with the position of this NGO on health effects of EMF.

Possible conflicts of interest

His Declaration of Interests statement to ICNIRP, says that he does paid consultancy but “non-relevant to ICNIRP”.

According to AVAATE this is not really true: “He gave expert witness testimony on behalf of the defendants in a January 2012 lawsuit in Federal District court in Portland, Oregon.”

A company AHM Wireless sued the Portland Public School System, because it called for the removal of a Wi-Fi system in the schools. The testimony of Savitz was requested to assess the expertise of plaintiffs' claims that the implementation of wireless devices and wireless systems in the schools could possibly cause cancer or other adverse health effects.

In court, he states that the purpose of his contract with Battelle was to investigate relationships between environmental agents and human health and that he had a variety of sponsors, including some federal government agencies and other groups that he does not recall at this time.

Remarkably when he is asked about his ICNIRP membership he said that doesn´t consider himself to be really an active member and that he contributed all those years to just four reports, together with Anders Ahlbom, who coordinated their advice work for ICNIRP and whom had also recruited Savitz to join ICNIRP (in 2011 was asked to step down from IARC panel after he was exposed to be on the board of his brother's consulting firm, which telecom clients). Savitz: "My understanding of the organization is really actually quite limited. My role in it has been much narrower to participate in the evaluation of evidence and the reporting of the results of that evaluation. I have not been involved in what's done with that evaluation."

When the lawyer of the public school asks "So the organization, though, it's involved with the protection of human beings from non-ionizing radiation; is that correct?" Savitz answers: "Again, my understanding is not much deeper than as you described it based on the name of the organization. My understanding is that they evaluate evidence and make recommendations that are intended to be protective of health."

When asked if he is paid to be part of scientific committees, he says that he remembers only travel expenses being reimbursed by ICNIRP. He says he doesn´t even remember how many scientific committees he belongs to. He wasn´t involved with what ICNIRP does in making decisions after it receives the results of the evaluation carried out by the Standing Committee on Epidemiology. He says that he has never read the ICNIRP Statutes, its mission, etc. He maintains that he is hired to help evaluate a particular line of research. Also, when asked if there was any relationship between ICNIRP and the WHO for the work in which he contributed to, he said he did not know.

It almost seems as if Savitz does not want to be remembered too much about ICNIRP and tries to distance himself from the NGO and its position. When the lawyer of the public schools asks "you would agree then that we need protection from non-ionizing radiation; is that correct?", Savitz answers: "Well, that's not something that I get involved in the technical judgment of the sort of guidelines or regulations or decision-making. If you're asking, obviously there are levels of exposure that I'm aware that can be harmful, so that I can understand in a general way that it makes sense that there be consideration of regulation."

AVAATE notes that "when asked whether he has been paid out of funds acquired from companies and/or telecom consultants and law firms that represent these companies, he replied that there are a few cases where he has done research funded by the electric utility industry. However, he emphasized that the funders tried to isolate his work from the source of funding. He says he once had done a study before realizing where the money came from."

Savitz also stated that he has done work sponsored by EPRI, as many ICNIRP members, which is funded by the electrical power industry.

There is no record of these kind of data in the Declaration of interests that he submitted to ICNIRP.

Karl Schulmeister

Biography

Karl Schulmeister is since 1994 head of the Laser, LED and Lamp Safety group at Seibersdorf Laboratories in Austria. On his LinkedIn profile he describes himself as 'Consultant on Laser and Optical Radiation Safety'.

He was a member of the ICNIRP Standing Committee on Optical Radiation in the period 2008-2012 and joined the Scientific Expert Group in March 2013.

Position

Karl Schulmeister is specialized in optical radiation. He did not perform research on the health effects of radiofrequency radiation.

Possible conflicts of interest

Seibersdorf Laboratories is a firm, not an academic institution. Schulmeister's group derives, according to his Declaration of Interest, about 10% of its income from paid consultancy.

Research for an article published in 2015 and a white paper published in 2016 received both the support of the Laser Illuminated Projector Association, which presents itself as "a single industry voice in rationalizing laser regulations".

David H. Sliney

Biography

Sliney serves as chair of the IES Photobiology Committee and holds a Ph.D. in biophysics and medical physics from the University of London, Institute of Ophthalmology. He worked for the US Army Public Health Center for 42 years, serving as Program Manager, Laser/Optical Radiation Program, until retiring in 2007.

Het still acts as Safety Director, American Society for Lasers in Medicine and Surgery; And he remains an associate faculty member of the Johns Hopkins School of Public Health, Department of Environmental Science and Engineering, Baltimore, MD.

He served as member, advisor and chairman of numerous committees that are active in the establishment of safety standards for protection against non-ionizing radiation (ANSI, ISO, ACGIH, IEC, WHO, NCRP).

He has been an ICNIRP Commission Member from the very start in1992 until 2004 and as Chairman of ICNIRP SCIV (optical radiation) from 1998 until 2004. He is a member of the ICNIRP Scientific Expert Group (SEG) since November 2017.

Position

Sliney has been mainly focussing on safety and health issues of laser lights, UV light or other sources, important for safety for medical staff who work with laser application in surgery and medicine. Also, scientists and military staff are risk groups for laser damage to the eye. We could not find research on the health effects of radiofrequency radiation.

Which does not mean that he is not involved in the scientific debate. In 2013 for example he participated in a webinar by the American Conference of Governmental Industrial Hygienists (ACGIH) on electromagnetic radiation.

In an article from 2017 on the history of of ICNIRP founder Mike Repacholi explicitly gives a special thanks to long-term INIRC and ICNIRP member David Sliney for his help with reviewing the article.

In a book from 2000 in 'the NATO Science Series' by B.Jon Klauenberg (US Air Force Research Laboratory) and also NATO-liaison, Sliney is described as "Dr Dave Sliney and army employee who serves on the ICNIRP". Klauenberg who in the first years led the WHO EMF Project together with Repacholi, is a prominent figure from the US Department of Defense (DOD) and describes it as follows: "Because the US military services operates globally and with many different national partners, uniformity of the RFR exposure standards is a desirable goal." He then describe the various ways that the DOD contributes to "worldwide standards harmonisation". So, the DOD participates in the WHO EMF project for example "through active engagement of US Air Force Research Laboratory as well as US army personnel providing service on the IEEE". And Sliney thus seems to be the US army representative in ICNIRP.

Possible conflicts of interest

His DOI is signed in 2019 but does not mention much.

Rianne Stam

Biography

Rianne Stam is senior scientist at the National Institute for Public Health and the Environment (Bilthoven, the Netherlands) since 2007. There she performs risk assessments and policy research on the biological effects and possible health risks of electromagnetic fields (EMF).

She is a member of the Scientific Expert Group since March 2013.

Position

Stamm made in 2015 and 2019 overview reports of the long term effects of electromagnetic fields on the health of workers. The conclusion: 'Scientific research has not yet proven any links between the exposure of workers and the occurrence of cancer, disorders of the nervous system or other illnesses in the long term.'

Possible conflicts of interest

According to her ‘Declaration of Personal Interest’ Stam has no possible conflicts of interest and we did not find any information that contradicts this.

Bruce Stuck

Biography

Bruce E. Stuck He is now retired. He was from 1992-2010, the Director of the U.S. Army Medical Research Detachment of the Walter Reed Army Institute of Research, where he had responsibilities for the Army Medical Department’s laser and radio frequency radiation biological effects research program. Until 2013 he was the Director of the Ocular Trauma Research Division at the U.S. Army Institute of Surgical Research in San Antonio, Texas.

Since 2012 Stuck is a part-time independent consultant on non-ionizing radiation bioeffects.

He has been a member of ICNIRP SC IV since 1999 and of the Commission from 2004 until 2016. Stuck is now supporting the work of the Project Group as a SEG member.

Position

His research focussed on laser and radio frequency radiation biological effects and “establishes protection strategies (e.g. exposure limits or physical protection products) and develops triage and treatment approaches for ocular injury from non-ionizing radiation and shock wave exposures from blast”. During his 32 years-experience in laser hazards research experience he was author/co-author of numerous papers on ocular and cutaneous effects of laser and radio frequency radiation. His primary interests are in the biological effects of visible and infrared laser radiation on the retina and cornea and the assessment of laser-induced eye injuries and their treatment.

Possible conflicts of interest

His DOI states that he is “a consultant to Perfect Lens, LLC on a proprietary project under a signed confidentiality agreement to provide advice and written assessment on biological exposure limits as applied to their repetitively pulsed fem to second laser application for use in medical application in the eye”. He delivered oral and written reports on the device hazard assessments. Income was less than 1% of personal income from his retirement annuity in 2018 tax year.

John Tattersall

Biography

John Tattersall **i**s scientist in the Defence Science and Technology Laboratory, a government Agency which provides research and advice for the UK Ministry of Defence and other government departments. He also is Honorary Senior Lecturer in Clinical Neurosciences at the University of Southampton.

He was a member of the IEEE International Committee on Electromagnetic Standards from 2012 until 2017.

He joined the Scientific Expert Group in March 2013.

Position

Twenty years ago, Tattersall did research that showed effects of RF Radiation on the brain of rats. *New Scientist* wrote: "Last year, fears about mobiles affecting brain function received fresh impetus thanks to work by John Tattersall and his colleagues at the Defence Evaluation and Research Agency's labs at Porton Down in Wiltshire. Tattersall exposed slices of rat brain to microwave radiation. He found that it blunted their electrical activity and weakened their responses to stimulation. Because the brain slices were taken from the hippocampus, a structure with a role in learning, the results were seized upon as further evidence that mobile phones could scramble human memories."

But according to later research these effects were artificial, "may be explained by localised heating produced by interaction of the RF fields with the recording and stimulating electrodes".

Tattersall was involved in the new guidelines that were published in 2020.

Possible conflicts of interest

For IEEE/ICES see Van Rongen and others.

Tim Toivo

Biography

Tim Toivo works as senior inspector for the Radiation and Nuclear Safety Authority STUK in Helsinki, Finland. He is mainly involved in regulatory, research and expert work in the area of safety issues of electromagnetic fields (EMF) and ultrasound.

He studied biomedical engineering at Tampere University of Technology 1996. And started his work at STUK–Radiation and Nuclear Safety Authority in 1998 as a scientist in the unit of non-ionizing radiation.

Part of his work is to inform users of EM fields and communicate with the general public about safety issues. He participated in the preparation of the EU directive (EU 2013/35/EU) as an expert for the Finnish delegation.

He is a member of the ICNIRP Scientific Expert Group (SEG) in February 2017.

Position

Toivo was quoted in the book 'Behind the Screen: Nokia's success story in an industry of navel-gazing executives and crazy frogs': "It is fairly easy to prove that something is hazardous, but it is extremely difficult to prove that something is totally safe under all circumstances. It may take 20-30 years before any meaningful results are available from people who have been exposed to low power radiation."

In 2009 STUK published a position that 'children's mobile phone use should be limited.

A publication in 2006 – 'Epidemiological risk assessment of mobile phones and cancer: Where can we improve?' - together with Anssi Auvinen, concluded that "the major opportunity to improve the quality of evidence is, however, through prospective studies. The major limitation of epidemiological studies addressing the health effects of mobile phone use is related to exposure assessment. These limitations are inherent in case–control studies."

A 2008, in Vitro study of Pulsed 900MHz GSM Radiation on human Spermatozoa showed no effect.

In a 2009 publication – 'Specific absorption rate and electric field measurements In the near field of six mobile phone base station antennas' - Toivo and colleagues seem to suggest that the ICNIRP safety standards are very conservative: "It was also shown that the ICNIRP basic restriction for local exposure could be exceeded before the basic restriction for whole-body exposure if the distance to the antenna is less than 240mm."

With several ICNIRP colleagues he published the 'Progress report: ICNIRP Statement on non-ionizing radiation for cosmetic purposes' for the IEEE. They concluded that "'for cosmetic devices using radiofrequency EMF and optical radiation, there is the potential that occupational exposure limits can be exceeded if adequate protection measures are not applied."

Possible conflicts of interest

Hid DOI states that he gets funds from ministries which go directly to the Radiation and Nuclear Safety Authority STUK.

Andrew Wood

Biography

Wood is Professor in Bioelectromagnetic Research Group at Swinburne University of Technology in Melbourne. He also is a Chief Investigator with the new Australian Centre for Electromagnetic Bioeffects Research (a centre to which Rodney Croft and Sarah Loughran are also connected).

Wood used to work at Telstra Research Labs and is now a leading researcher at Swinburne Radiofrequency Dosimetry Laboratory, which is a part of the Bioelectomagnetic Research

Group. Telstra is Australia's largest telecommunications company. Swinburne university and in particular the Radiofrequency Dosimetry Laboratory has close relationship with and is co-funded by Telstra, the biggest Telecom company in Australia.

The close working relationship between the Swinburne University and Telstra is not new, as Don Maisch pointed out: "In fact the Chancellor of Swinburne University, Mr. Bill Scales (2005-2014) was previously Telstra's Group Managing Director, Regulatory, Corporate and Human Relations, and Chief of Staff at Telstra. He was also Telstra's Director of IBM Global Services Australia Ltd. and a Director of the Telstra Foundation."

Wood was a member of the Radiation Health Committee of the Australian Radiation Protection and Nuclear Safety Agency (ARPANSA) for over ten years.

He is a member of the Scientific Expert Group since March 2013.

Position

Wood does not see dangers of 5G and warns for being too cautious: "Wireless technologies bring enormous benefits, and being over-cautious would potentially deny these benefits to needy communities."

In a recent article he stated that studies which show health effects have a poor quality: "There are some comprehensive reviews of these, demonstrating that the quality of the studies is very variable, and that, for example, results claiming to show increased genetic damage or other biological effects are much more common in studies of low quality, whereas higher-quality studies predominantly show no significant effects."

Possible conflicts of interest

In a 2016 publication that gave an overview of the work Wood's group performed he and his co-authors wrote: "Over its 25-year history the Bioelectromagnetics Group has received support from national competitive grants and from industry research support schemes. It has been a node for both the Australian Centre for Radiofrequency Bioeffects Research (ACRBR) and the Australian Centre for Electromagnetic Bioeffects Research (ACEBR—see article in this edition). It has benefitted from industry collaboration and with national regulatory authorities."

The close collaboration with industry we see time and again. Just like the actual chair of the ICNIRP-commission Croft, Wood had actively collaborated with McKenzie, who is a manager at the Mobile Carriers Forum (MCF). See for more information the portrait of Croft.

In 2016, he published an article together with an employee of telecommunications company Telstra.

He has done contract work on the issue of smart meters for the private company EMC Technologies Pty Ltd.

According to his Declaration of Personal Interest he receives research support "from two engineers employed by Telstra Corp and one by the Australian Mobile Telecommunications Association."

Tongning Wu

Biography

According to ICNIRP's website Tongning Wu is a senior engineer in the Chinese Academy of Information and Communications Technology. His research focusses on electromagnetic dosimetry, anatomical modelling and biomedical applications of electromagnetic fields.

He is the member of International Advisory Committee (IAC) on Electromagnetic Fields of WHO. He also participated in the IEC/IEEE workgroups on EMF safety. He is currently the co-rapporteur of ITU-D Q7/2 (Strategies and policies concerning human exposure to electromagnetic fields).

He became a member of the ICNIRP Scientific Expert Group (SEG) in 2019.

Position

Wu agrees with the general ICNIRP assessment that "to date, no adverse health effects of the EMF, linked to these applications, have been established." This was also one of the conclusions of a study 'Electromagnetic fields (EMF) exposure' published in 2019.

In 2012 WU published a study on 'A large-scale measurement of electromagnetic fields near GSM base stations in Guangxi, China for risk communication'. The results were that "in general, the measurement mission promotes the science on EMF exposure among the general public. Risk-related public behaviours have been positively influenced. The mission also facilitates the cooperative conflict resolution. It helps strengthen the effectiveness of risk communication."

Possible conflicts of interest

His DOI gives no information.

See Van Rongen and others on the role of IEEE/ICES.

Annex I

Questions put to ICNIRP's secretariat

1 - When will the ICNIRP Annual report 2019 be published?

2 - Are the 14 members of the Commission being paid for their work for ICNIRP (for "representing ICNIRP externally and mostly in its relations with the international and national partners and the press" as well as for their collaboration on specific Projects?)

3 - Same questions as n° 2 go for the Scientific Expert group and the Project Groups?

4 - If they are not paid, do you consider this as a normal practice that international renowned experts work for free, especially given the importance and influence of the work of ICNIRP?

5 - ICNIRP itself claims it is "free of vested interests". ICNIRP's budget relies on support granted by public bodies; Why is the income not specified in your annual reports? Is it possible to get specifications from which public bodies you get which amounts?

6 Who selects the 14 members of the Commission and how?

7 - ICNIRP's statutes state: 'No member of the Commission shall hold a position of employment that in the opinion of the Commission will compromise its scientific independence'

Do we understand it correctly that basically the Commission evaluates itself about possible conflicts of interest? What are the rules by which the Commission judges if interests of the members compromise the scientific independence?

8- In its statement on the declarations of interests ICNIRP states: "The evaluation of personal integrity is very complex and might never be achievable in a perfect way. It is the duty of the ICNIRP Commission to carefully consider and decide if the declared interests potentially constitute a conflict of interest."

By which criteria or protocol are these considerations and decisions being made?

9- Do you consider the membership of IEEE ICES by some ICNIRP-members as a possible conflict of interests?

10- How do you explain the fact that a private organisation like ICNIRP, which is not accountable in democratic terms to anyone, has the position to de facto "determine" via guidelines the EMF policies of most EU member states?

Several attempts to get a reaction to

these questions remained unanswered'

Annex II

Questions put to emfproject@who.int

On your website, you write: "Because disparities in EMF standards around the world has caused increasing public anxiety about EMF exposures from the introduction of new technologies, WHO commenced a process of harmonization of electromagnetic fields (EMF) standards worldwide. With 54 participating countries and 8 international organizations involved in the International EMF Project, it provides a unique opportunity to bring countries together to develop a framework for harmonization of EMF standards and to encourage the development of exposure limits and other control measures that provide the same level of health protection to all people. "

1 - Is there a time schedule for this process of harmonization of electromagnetic fields (EMF) standards worldwide?

2 - We see on your website that the last EMF -WHO meeting took place in 2018. Are there any new meeting planned and if yes when?

3 - Do you know what IARC is currently working on and if so when will IARC publish an update of the monograph?

https://publications.iarc.fr/Book-And-Report-Series/Iarc-Monographs-On-The-Identification-Of-Carcinogenic-Hazards-To-Humans/Non-ionizing-Radiation-Part-2-Radiofrequency-Electromagnetic-Fields-2013

4 - How do you consider the debate on "conflicts of interests" in this specific research area? Would you agree that there has been and still is a lot of attention for this debate? Has his debate been useful in narrowing the divide in the scientific community? What is in your view the role of the WHO on this?

(see for example this recent letter published in "Bioelectromagnetics": https://onlinelibrary.wiley.com/doi/full/10.1002/bem.22225)

Citation of this article: Davis DL., Pilarcik, AM., Miller, AB. (2020) Increased Generational Risk of Colon and Rectal Cancer in Recent Birth Cohorts under Age 40 - the Hypothetical Role of Radiofrequency Radiation from Cell Phones. Ann Gastroenterol Dig Dis, 3(1): 09-16.

Abstract

To determine if there are shifts in patterns of cancer, rates of disease can be evaluated in terms of Generational Risk (GR), comparing those born recently with those born decades earlier. Using data from the U.S. Centers for Disease Control and Prevention (CDC), the U.S. Surveillance Epidemiology and End-Results (SEER) Program and Iranian cancer registries, increases in GR of colon and rectal cancer in those under age 50 are presented. For the U.S. those born in the 1990s have a doubled risk of colon cancer (GR=2) and a fourfold increase in rectal cancer (GR=4) by the time they reach age 24 compared to those born six decades ago. Experimental studies have determined that the colon and rectum of Sprague-Dawley rats are exquisitely sensitive to both ionizing and non-ionizing radiofrequency radiation (RFR), expressing significant differences in patterns of methylation of a number of well-identified proteins and other biomarkers predictive of cancer risk. Modeling of nonionizing exposures also indicates that absorption of RFR into the colon and rectum from cell phones stored in the pocket exceeds current test limits by up to 5-fold. French government tests of phones positioned next to the body report exposures to non-ionizing radiation that are up to 11 times more than current guidelines. Based on these findings, it is prudent to develop policies to reduce direct exposures to RFR from cell phones, as occurs when they are kept next to the body, and to promote advances in hardware and software that reduce direct exposures to RFR.

Keywords: Computerized tomography, Radiofrequency radiation, Colo-rectal cancer, Cell phones, Generational risk

Abbreviations: ALARA: as Low as Reasonably Achievable; CDC: Centers for Disease Control; CRC: Colo-rectal Cancer; CT: Computerized tomography; GR: Generational Risk; GSM900: Global System for Mobile Communication; RFR: Radiofrequency Radiation; RAR: Retinoic Acid Receptor; SEER: United States Surveillance Epidemiology and End-Results Program; US: United States

Colorectal cancer (CRC) is the third most common cancer in the world, and the fourth leading cause of cancer deaths, with about 700,000 estimated annually [1].While incidence is greater in developed nations, deaths from the disease are more common in rapidly developing nations that lack the infrastructure to fi d and treat the disease. As with most types of cancer, rates of CRC increase with age. The disease remains relatively rare in young persons. While there has been a major increase in incidence globally [2,3]. Overall rates are dropping in the U.S. and Europe [1], but not all age groups share in that decline. The proportion of persons under age 50 diagnosed with the disease has doubled since 1990, from 6% to 13% in 2017.

Epidemiological studies have identifi d a number of specific risk factors for CRC including obesity, inactivity, diets high in red and cured meat, alcohol, smoking, and other factors [4]. Tremendous changes of dietary habits have occurred in both the developed and the developing world during the last decades. Recorded overall declines in CRC in those over age 50 in the U.S. and elsewhere are generally attributed to improvements in screening with colonoscopy and other procedures and do not refl ct reductions in these known risk factors. Surgical removal of pre-cancerous polyps is believed to account for much of the decline in CRC in the elderly. While improvements in access to care and increases in diagnostic ascertainment may in part account for these continued declines in the elderly, they are unlikely to account in any signifi ant way for increases that occur in those under age 50 in whom screening is neither recommended nor conducted. Inherited germ-line mutations, such as Lynch syndrome, are responsible for about 5% of all disease [5].

Th s review fi st explores trends in Generational Risk (GR) of CRC in order to document patterns in younger and older persons [5]. Secondly, potential explanations for these patterns are investigated, concentrating on the increase in exposure to non-ionizing radiation that has occurred world-wide, including the young. Finally, prudent precautionary policies in the light of these fi dings are advised.

We examined colon and rectal cancer incidence data from the national cancer registry of the U.S., the U.S. Centers for Disease Control and from the Iranian national cancer registry. Patterns were evaluated for secular time trends and in terms of birth cohorts, using established methods for determining GR, contrasting incidence in those born after 1990 with those born before 1950. Novel toxicological investigations of CRC cells response to ionizing and non-ionizing radiation are also presented as they provide clues regarding possible etiologic factors that could underlie these patterns of disease and inform policies aimed at reducing risk factors.

Figure 1 reveals contrasting patterns of CRC cancer for older and younger Americans. There are major declines in incidence of CRC in those over age 54, in whom 90% of all CRC occurs. In contrast, a countervailing pattern is evident in those born after 1950, with a marked increase in the past two decades of CRC incidence in those born in 1970 or later compared with rates in those under age 40 in the past two decades. Employing the GR model we conclude that by the time they reach age 24 those born after 1970 are developing more than four times more rectal cancer (right side of figu e) and twice the rate of colorectal cancer (left side of fi -ure) compared to those born before 1940. Because the numbers of cases are quite small, the standard deviation in the rates will be considerable for those in their twenties. Nonetheless, the sharp increase in rates for younger birth cohorts in whom improved access to diagnostic technology is not a likely factor signals that there is a real underlying surge in CRC underway in the young. Siegel, et al. [6] recently evaluated patterns of colon and rectal cancer in the U.S. in the 4 decades up to 2013. They found that in contrast with the modest annual increases in colon cancer of less than 1% annually for all age groups under age 55, trends in incidence of rectal cancer are considerably greater with rates growing most rapidly and sharply in those ages 20-29 in the past decade. Specifically, rectal cancer incidence rates increased annually 3.2% from 1974 to 2013 in adults age 20 to 29 years, but more recently grew 4.0% annually. In contrast, for that age 55 and over rates generally declined throughout the entire 40-year study period. Similar fi dings have been reported from Europe and Iran [7,8].

Patterns of CRC in Iran (Figure 2) are illuminating as they indicate that for both men and women of all ages, incidence has recently risen sharply, from about 2 per 100,000 in 2000 to more than 8 and 10 per 100,000 respectively in females and males, an increase of 4 to 5-fold. Moreover, combined rates of colon and rectal cancer have risen from 5 per 100,000 in 2001 to more than 20 per 100,000 in males in 2011. In Iran, surgeons are reporting more cases of the disease in younger patients (Masood Sepephrimanesh, personal communication).

In an effort to determine whether radiofrequency radiation could be affecting rates of CRC, Iranian scientists from the Ionizing and Non-ionizing Radiation Protection Research Center of Shiraz University of Medical Sciences have reported on a series of basic research studies where they devised, validated and evaluated special chemical fi gerprints for relevant cellular patterns by staining genetic and epigenetic factors associated with CRC carcinogenesis. The biochemical elements they examined include the estrogen receptor, and genes believed to be critical to inflammatory processes, including COX2, APC, MINT, and MLH1 gene promoters that may represent early stages of colorectal carcinogenesis [9,10]. The grounds for incorporating and examining these biological indicators derive from several studies that have found that a number of these well-identifi d proteins are hypermethylated in CRC: ER alpha and MYOD, p53 the cell cycle regulatory gene, cyclin A1, UDP-glucoronosyl transferase and retinoic acid receptor. Thus, it is possible that alterations in patterns of methylation in these genes may well constitute an early biomarker of colon carcinogenesis [11] and are considered by several investigators to be prognostic for a high risk of CRC malignancy [12]. A number of additional studies have recently confi med that methylation of ERα, MYOD, MGMT, SFRP2, P16, APC, DCC, MINT, COX2, HLFT, SOCS1, and hMLH1 gene promoters appear to have critical functions for the onset of colorectal carcinogenesis [9,10].

Mokarram, et al. [13] compared epigenetic patterns of ERα after exposure to ionizing radiation, with those occurring after exposure to non-ionizing radiofrequency radiation. Their innovative study employed biomarkers that have previously been established to signal damaging exposures to ionizing radiation, especially γ-rays. All groups studied in this experiment had methylated ER allele, while the un-methylated band varied considerably. While all of the control group displayed un-methylated bands, not one of the rats exposed to either radiofrequency or gamma radiation had any such bands. Th s indicates that methylation patterns may constitute an important validated biomarker of exposure to radiofrequency radiation that has the potential to play a role in the expression and promotion of CRC.

Recently, DNA hyper-methylation has been identifi d as a vitally important potential biomarker of cancer risk that can be used to predict rates of recurrence and advance of the disease and can be a signal property of several forms of cancer [11]. Hypomethylation of DNA may also control gene expression and chromosomal stability. Thus, ER alpha and MYOD, p53 the cell cycle regulatory genes, cyclin A1, UDP-glucoronosyltransferase and retinoic acid receptor are hypermethylated in CRC and also can be found in early stages of the disease [11]. Several investigators now consider that the methylation status of the ER promoter in the lymph nodes constitutes a valid biomarker for the development of advanced malignancy in CRC patients with stage I and II colon cancer and can be used to indicate the likelihood of disease progression [12].

The Iranian experimental study is important because as they note: "For the fi st time, our data showed that the effect of exposure to mobile phone radiation and 3Gy gamma radiation are the same and both of them could decrease the U-allele in the treated colon tissues of rats compared to the controls (p=.000)."

Further support for altered DNA methylation patterns as predictors of CRC comes from Dong and Ren [14]. They note that CRC results from a multi-stage, multi-causal process, refl cting the combined impacts of a variety of genetic and epigenetic changes in CRC cells that can be signaled through epigenetic alterations in blood. Using the Food and Drug Administration approved Virtual Family 3-dimensional, anatomically-based modeling of exposures to non-ionizing radiofrequency radiation carried out by the National laboratories of the Federal University of Brazil in Porto Alegre also indicates signifi ant absorption of non-ionizing radiation takes place within the pelvic area from phones stored in the pants pocket of men, with male reproductive organs absorbing the highest levels. The pelvis has a high dielectric constant and permittivity, because it is mostly soft tissue and fat, lacking the dense bone of the skull. As a result, radiation can be more deeply

absorbed into the pelvis as compared with the brain.

Despite general declines of rates of CRC in developed nations, especially in those over age 54, puzzling and substantial increases have been reported in younger persons in the U.S. and Iran [6-8]. Similar increases have been noted in Canada [15]. Population-based screening in developing nations is not widely conducted, so this cannot account for much of the reported increase in the disease in younger persons in Iran. It is important to appreciate that the underlying and distinctly diverging secular trends in colon and rectal cancer reported by these authors began decades before cellphones were widely in use. Screening certainly has played a role in the continuing decline in CRC in the elderly. But as to the unexplained relatively recent increases in the young, it is important to consider a number of potentially relevant causal factors that have changed in the past two decades. These include obesity and physical inactivity, increased exposures to HPV, HIV, and other viral factors, diagnostic radiation from computerized tomography and non-ionizing radiofrequency radiation (RFR) from cellphones, laptops, and other devices.

Belyaev [16] has noted that ionizing and non-ionizing radiation have a number of distinct properties including, polarity, wave form, power density, and frequency and that their importance to biological systems can vary with temperature, host conditions and other factors that are not always well-controlled in various studies of non-ionizing radiation. The GSM900 (Global System for Mobile Communication) includes 124 different channels/frequencies. They differ by 0.2 MHz in the frequency range between 890 MHz and 915 MHz. Depending on the number of connected users op-

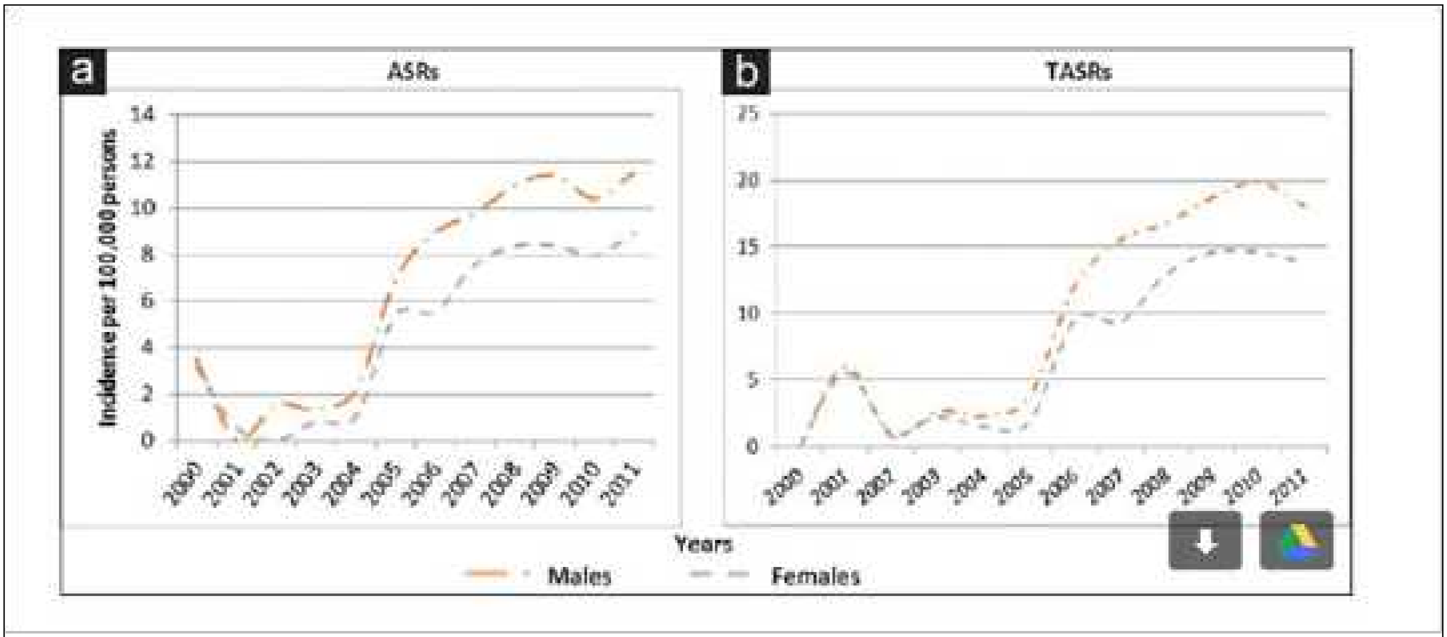

Figure 2: Trends in Age-Standardized Rates of Colorectal cancer in Iran 2000-2011. Source Dolatkhah, et al. [7]

erating at any one time, frequency is supplied by a base station to a mobile phone user and can be automatically changed to another frequency during the same call. Belyaev [16] also reports that contrary to differentiated cells, human mesenchymal stem cells do not adapt to effects of microwaves during chronic exposure. These results also suggest that less mature and differentiated cells, such as are more common in the young, may be more susceptible to proliferative responses.

When cell phones are stored next to the body, their four to six or more antennas continue to send signals to towers or hotspots up to 900 times a minute in search of an electronic handshake to maintain connectivity, especially when they are being employed when in motion. Because antennas are on the backs and sides of smartphones, keeping cell phones turned on in the pocket subjects users to frequent microwave radiation bursts. Putting cell phones on airplane mode eliminates exposures to radiofrequency radiation.

Both experimental and epidemiological evidence supports a role for RFR from cell phones in the pocket or laptop exposures. Avendaño, et al. [17] found that human sperm samples exposed ex vivo to levels of RFR from conventional laptops at a distance of 3 cm that were specially shielded not to produce battery heat developed signifi antly more genetic and epigenetic damage after 4 hours of continual downloading and uploading to simulate intense game-playing, video watching or other activities. Damage to human spermatozoa for 4 hours affected quality and quantity signifi antly--3-fold greater damage in exposed sperm in contrast to unexposed controls. These results are similar to those Houston, et al. [18] reported with in vitro studies of human sperm that found signifi ant evidence of such damage as oxidative stress, including the DNA damage marker, 8-hydroxy-2'-deoxyguanine as well as sperm fragmentation.

For the next decade it is expected that cell phones will need to rely on 3G and 4G for voice communications, even if 5G becomes available for speedier downloading movies, games, virtual reality and videos. It is important to point out that although absorption of faster, shorter millimeter waves of 5G alone will be superficial compared to earlier generations of 2G and 3G that reached 2 inches into the brain and much more deeply into the pelvis, there are growing concerns that these higher frequencies can produce unique biochemical reactions just below the surface of the skin that effectively transform them into more powerful systemic impacts on the immune system. Although millimeter wave exposures are absorbed into 1/64 inch of human skin, the beam-forming erratic properties of 5G signals may prove highly biologically reactive. It is possible that the sweat ducts in the human body will act as helical antennas, directing the millimeter waves deeper into the body, serving effectively as wave guides [19]. Moreover, some technologists have reported that, contrary to marketing claims that 5G is essential for autonomous vehicles, beam-forming properties are neither reliable nor easily controllable, and 4G systems are quite adequate to that task. Writing in a trade publication, technology writer and former industry executive, Desjardin [20], acknowledges that with respect to 5G no one has addressed questions of potential biological impact of complex modulation of 5G at 28.375 GHz, combined with 77 GHz from automotive radar, and 5.9 GHz from automotive infrastructure.

In addition, in considering the possible role of contemporary exposures to cellphone radiation for these unexplained patterns of CRC, it is important to consider recent reports from the French government frequency testing agency (ANFR) that most cell phones emit substantially more radiation than current test limits advise. Using FCC approved methods to conduct the testing, the agency found that 9 out of 10 phones exceeded the safety guidelines when held against the body by factors of 1.6-3.7 times for the European standard or by factors as high as 11 if 1-g SAR values were to be measured as required by the U.S. FCC [21].

Other exposures that appear relevant to these puzzling patterns of CRC include the greatly expanded use of pediatric diagnostic computerized tomographic (CT) scans. Brenner and Hall [22] estimated that a signifi ant proportion of young adult cancer in the future would refl ct CT practices that began in the 1980s, when the younger birth cohort was born. At that time, Brenner and Hall [22] reported that approximately 600,000 abdominal and head CT examinations were conducted annually in the United States on pediatric patients under the age of 15 years. Brenner and Hall [22] estimated that approximately 500 children might ultimately die of cancer attributed to CT radiation. By 2016, the number of CT scans conducted on both children and adults increased signifi antly to about 82 million. Although the average dose per procedure had declined, the average diagnostic radiation dose per individual has more than doubled since 1980. Currently, Americans, especially children, receive more ionizing radiation exposures from diagnostic radiation than from natural sources. The excessive use of this technology especially with infants and children led the American College of Pediatric Radiology to issue a white paper in 2007, urging that technologists be mindful of the need to keep pediatric exposures, As Low As Reasonably Achievable (ALARA). While current practices may reduce ionizing radiation overall, past scenarios involved emergency room physicians ordering repeat CT, even whole-body CT, where abuse was suspected.

Some recent evidence corroborating concerns about the long-term impacts of CT scans was provided by a retrospective study of 168,394 Dutch children that had undergone one or more CT scans, with those receiving the highest radiation having the greatest risk of brain tumors [23]. Another investigation in the UK, found that those under age 22 that underwent CT scans between 1985 and 2002 had greater risks of developing both brain cancer and leukemia [24].

In considering other known risk factors for CRC, such as obesity and inactivity, it is instructive to note that changes in these propensities have not changed as much as the rates we report here. Thus, obesity in adults 20-74 has more than doubled since 1979 and was 35% greater in 2014 [25]. However, because the latency for colorectal cancer is thought to be a decade or longer, changes in obesity are unlikely to explain much of the recent surge.

The studies reviewed here confi m statistically signifi ant and unexplained patterns of increase in CRC in younger persons. As a multi-factoral, multi-causal disease, cancer has numerous causes. While germ line mutations are relevant in about 5% of all cancer cases [26], the bulk of CRCs stem from acquired mutations that arise as a consequence of interactions with xenobiotic agents. The appearance of increased rates of this disease in younger persons is a matter that merits the most serious concern. Improved screening or use of technologies to increase diagnostic ascertainment such as improved imaging and greater access to endoscopy as well as general improvements in health care in this younger age group seem unlikely to account for these patterns.

We suggest two plausible contributing factors underlying these unexplained increases in CRC in the young—increased exposures to RFR from cell phones and laptops and/or increased exposures to ionizing radiation through CT scans. While obesity and inactivity are also important considerations, changes in these factors cannot in and of themselves account for the changes reported here. One of the attractive aspects of these proposed risk factors is that they can be easily addressed through education of health professionals and the general public, unlike lifestyle determinants such as diet and exercise.

The possibility that RFR and/or CT exposures in childhood could contribute to CRC in young adults should be accorded prompt attention. Methylation patterns in CRC are similar for both ionizing and non-ionizing radiation. Anatomically-based modeling investigations confi m that exposures to the colon and rectum appear to be quite substantial from cell phones held next to the body (in the pocket) and French test data show that typically cell phones emit many-fold more RFR than current test guidelines allow. Thus, it appears prudent to promote policies to reduce exposures to radiofrequency radiation and encourage ALARA during pediatric CT procedures, while continuing to promote advances in software and hardware of phones and scanners that can lower exposures to non-ionizing radiation during normal operations. In addition, major public educational programs should be developed to promote awareness of the need to practice safer technology, especially for the young, who may well be at greater risk of developing cancer due to their immunological immaturity.

The authors declare that they have no confli ts of interest in relation to this review.

Health Matters

Science, Politics, and Groupthink

■ James C. Lin

The onset of the COVID-19 coronavirus in early 2020, lasting through the end of the year and beyond, has undoubtedly rendered 2020 incredible in many ways. COVID-19 has caused a devastating global pandemic with rapidly increasing case counts and deaths. Globally, the numbers of confirmed cases and fatalities exceed 83,113,878 and 1,812,218, respectively. In the United States, there were 19,821,487 confirmed cases and 343,818 deaths as of the end of 2020 [1]. It boggles the mind how COVID-19 descended into a conspiracy theory, pitting politics against science while millions of lives have been lost and so many more have pointlessly suffered from grief and pain. It does not seem to make sense.

James C. Lin (lin@uic.edu) is with the University of Illinois at Chicago, Chicago, Illinois, 60607, USA.

Why? Is it because science got wrapped up in politics, or is it politics interfering with science? Perhaps, the better or more practical questions are how much politics should be influenced by scientific findings and whether politics should intervene when science upsets the established political order enough to justify governmental action. These questions are not new or groundbreaking.

©SHUTTERSTOCK.COM/DENNY DAVIDSON

Nicolaus Copernicus, a 16th century Polish astronomer, set forth the revolutionary view that Earth revolved around the sun and proposed a model of the universe that places the Sun rather than Earth at the center of the universe. Approximately a half-century later, Galileo turned his telescope to the heavens and saw the Milky Way with its numerous stars and the pockmarked surface of the moon and recognized that Jupiter has four moons of its own. Galileo traveled to Rome to meet with church leaders to present his discoveries supporting Copernicus' revolutionary view and to make the case for heliocentrism—that Earth moved around the Sun.

Instead, Galileo was condemned by the Holy Office of the Inquisition as heretical for holding the belief that the sun is the center of the universe, which was considered false and contrary to the Sacred and Divine Scripture. It was a dangerous idea, and one that cost Galileo his freedom. He was sentenced to imprisonment, followed by confinement for the rest of his life.

One may shrug off these ancient and modern incidents as episodic and proclaim them as absurd: to paraphrase *Ecclesiastes* 1, "Nothing is new under the Sun. Make no mistake, if it has not been found, it is there to be discovered; if it has not happened, it will only be a matter of time."

Fast forward to the 21st century, when, in 2011, the World Health Organization's International Agency for Research on Cancer (IARC) classified exposure to RF radiation as 2B—a possible cancer-causing agent to humans. The IARC had evaluated the then-available scientific studies and, although evidence was incomplete and limited (especially regarding results from animal experiments), concluded that the epidemiological studies of humans reported increased health risks for long-term users of cellular mobile telephones. These risks included gliomas (a type of malignant brain cancer) and acoustic neuromas (or acoustic schwannomas—a nonmalignant tumor of the auditory nerves on the side of the brain). This evidence was sufficiently strong to support a classification of exposure to RF radiation possibly being carcinogenic for humans [2], [3].

In 2018, the National Toxicology Program (NTP) of the U.S. National Institute of Environmental Health Science (NIEHS) reported observations of two types of cancers in laboratory rats that were exposed, for their entire lives, to RF radiation used for 2G and 3G wireless cellular mobile telephone operations [4], [5]. This is the largest health-effect study ever undertaken by the NIEHS/NTP for any agent. A 12-member peer review panel of independent scientists convened by NIEHS/NTP evaluated the toxicology and carcinogenesis studies and concluded, among other observations, that there was statistically significant and "clear evidence" that the RF radiation had led to the development of malignant schwannoma in the heart of male rats.

Shortly after the NTP report, the Cesare Maltoni Cancer Research Center at the Ramazzini Institute in Bologna, Italy, published the results from its comprehensive study on carcinogenicity in rats with lifelong exposure to 2G/3G 1,800-MHz RF radiation [6]. The study involved whole-body exposure of male and female rats under plane-wave equivalent or far-zone exposure conditions. A statistically significant increase in the rate of schwannomas in the hearts of male rats was detected for 0.1-W/kg RF exposure. It is critical to note that the recent NTP and Ramazzini RF exposure studies presented similar findings about heart schwannomas and brain gliomas. Thus, two relatively well-conducted RF exposure studies, employing the same strain of rats, showed consistent results of significantly increased cancer risks from mobile phone exposures.

Recently, a privately constituted group, with self-appointed membership, published a set of guidelines for limiting exposure to RF electromagnetic fields in the 100-kHz and 300-GHz frequency range [7]. The proposed guidelines were primarily based on the tissue-heating potentials of RF radiation to elevate animal body temperatures to greater than 1° C. While recognizing that the two aforementioned studies used large numbers of animals, best laboratory practice, and animals exposed for the entirety of their lives, the private group preferred to quibble with alleged "chance differences" between treatment conditions and the fact that the measured animal body core temperature changes reached 1° C, implying that a 1° C body core temperature rise is carcinogenic, ignoring the RF exposure. The group then pronounced that, when considered either in isolation or within the context of other animal carcinogenicity research, these findings do not provide evidence that RF radiation is carcinogenic.

Furthermore, the group noted that, even though many epidemiological studies of RF radiation associated with mobile phone use and cancer risk had been performed, studies on brain tumors, acoustic neuroma, meningioma, and parotid gland tumors had not provided evidence of an increased cancer risk. It suggested that, although somewhat elevated odds ratios were observed, inconsistencies and limitations, including recall or selection bias, precluded these results from being considered for setting exposure guidelines. The simultaneous penchant to dismiss and criticize positive results and the fondness for and eager acceptance of negative findings are palpable and concerning.

In contrast, the IARC's evaluation of the same epidemiological studies ended up officially classifying RF radiation as possibly carcinogenic to humans [2], [3].

An understandable question that comes to mind is this: How can there be such divergent evaluations and conclusions of the same scientific studies? Humans are not always rational or as transparent as advertised, and scientists are not impervious to conflicts of interest and can be driven by egocentric motivations. Humans frequently make choices and decisions that defy clear logic.

Science has never been devoid of politics, believe it or not. Here are a couple of cases in point.

Most people would readily say that the brilliant, celebrated Albert Einstein was a Nobel Laureate, having received the prize in physics. When asked about the subject of his research or scholarship, the default answer is "the theory of relativity" or "his observation of energy and mass being interchangeable (i.e., $E = mc^2$)." The response would rarely be otherwise. In fact, Einstein received his Nobel Prize in 1922 "for his services to theoretical physics, and especially for his discovery of the law of the photoelectric effect." Today, no knowledgeable physicist would dispute that Einstein deserved the Nobel Prize for his discovery of the photoelectric effect [9]. There lies the rub or paradox.

Among the many theories that Einstein had reported in the previous

17 years, his 1905 paper on photoelectric effect was a relatively minor contribution at the time, and it was the theory least accepted by contemporary theoretical physicists.

Cellular mobile communication and associated wireless technologies have proven, beyond any debate, their direct benefit to humans.

During the selection process in 1921, the Nobel Committee for Physics decided that none of that year's nominations met the criteria as outlined in the will of Alfred Nobel. However, Einstein was so renowned by that time that their failure to award him the prize had become an embarrassment. So the selection was a political decision by the Nobel Committee, most notably revealed by the insertion of "for his services to theoretical physics" as a telltale in the award citation. Regardless, the Nobel Committee exhibited courage and made amends for a major error.

The Nobel Prize in Physiology or Medicine for 2003 was awarded jointly to Paul Lauterbur and Peter Mansfield [10] "for their discoveries concerning magnetic resonance imaging." The award recognized the two Laureates' pioneering contributions, which led to the application of magnetic resonance imaging (MRI) in medical diagnostics and research. The discovery was a breakthrough in radiology, based on noninvasive and nonionizing radiation. MRI has significantly improved the diagnosis of numerous diseases and reduced risk and discomfort for patients. The announcement also led many to notice the absence of Raymond Damadian for his share of the Nobel Prize [11], [12].

Published records show that Damadian conceived of noninvasive magnetic resonance scanning, discovered tissue proton relaxation and density differences that are crucial to MRI, and achieved the first human whole-body images. Lauterbur devised methods to reconstruct 2D images a year later. Mansfield developed a faster pulse-sequence technique that differed from Lauterbur's reconstruction method a couple of years later. It appears unequivocal that all three scientists made important contributions in launching medical MRI. Why, then, was the Nobel Prize awarded to two of them?

There was apparent disciplinary allegiance, or groupthink, within the magnetic resonance research community. Science got wrapped up in politics and interfered to label the earlier contributions as insignificant or less consequential. Unfortunately, this time, the Nobel Committee managed neither to either confront nor mitigate a needless dispute.

Biases can impair rational judgment and lead to poor decisions. Emotions can keep humans from being rational and prevent us from arriving at obvious conclusions. At times, humans systematically make choices and decisions that defy clear logic. Regrettably, the herd mentality or groupthink is as rampant today as ever.

Some years ago, I commented, "Science has become partisan. And the corollary, if science becomes partisan, is it science or politics, or would it be political science?" [8]. Perhaps, it is simply a matter of the willing being politically correct.

When decisions are not arrived at by prudently balancing the facts or are made via impaired rational judgment, it could lead to poor decisions through biases. Sometimes, such poor decisions may impact only a small number of individuals. However, in cases like COVID-19, millions of people may suffer the unjust and needless consequences.

Cellular mobile communication and associated wireless technologies have proven, beyond any debate, their direct benefit to humans. However, as for the verdict on the health and safety of billions of people who are exposed to unnecessary levels of RF radiation over extended lengths of time or even over their lifetimes, the jury is still out. When confronted with such divergent assessments of science, the ALARA—as low as reasonably achievable—practice and principle should be followed for RF health and safety.

Regarding ICNIRP'S Evaluation of the National Toxicology Program's Carcinogenicity Studies on Radiofrequency Electromagnetic Fields

Dear Editor:

IN THE International Commission on Non-Ionizing Radiation Protection (ICNIRP) note (ICNIRP 2019) on the evaluation of the recent carcinogenicity studies of radiofrequency electromagnetic fields (RF-EMF) in experimental animals, the authors made several incorrect statements that appear to be written to justify retaining exposure standards that were established more than 20 y ago. In fact, the ICNIRP note concludes, "…if the research was shown to have relevance to humans, this would represent a crucial issue for ICNIRP to incorporate into the advice and guidance that it provides to the community through a range of formats, such as its RF EMF exposure guidelines." This correspondence focuses on correcting ICNIRP's false claims about the methodology, interpretation, and relevance of the National Toxicology Program studies on cell phone RF radiation (NTP 2018a and b). Several issues raised in the ICNIRP note were addressed by Melnick (2019) and in the NTP response to the initial reviews of the cancer findings in rats that are included in the NTP report of partial findings of the carcinogenesis studies of cell phone radiofrequency radiation (Wyde et al. 2016) but were ignored in the ICNIRP note.

ICNIRP wrongly claims that methodological issues "preclude drawing conclusions about carcinogenicity" from the NTP studies on RF radiation

Pathology review procedures

The NTP has provided results on the carcinogenicity of approximately 600 environmental and occupational agents. These results have been used by IARC (International Agency for Research on Cancer) and other public health agencies throughout the world to assess human risk and set health-protective exposure standards. The three-tier pathology review process is the most rigorous approach used by any research organization to identify neoplastic and non-neoplastic lesions associated with exposure to a test agent. The ICNIRP note claims that because the initial pathology examination was not blinded as to the dose group in which slides were read, there were biases in these histopathological evaluations. However, the NTP's pathology review process involves much more than "samples where pathology was found (i.e., only a few percent of the total number) were then analyzed by another pathologist who was partially blind to the exposure status." For all NTP studies, an independent quality assessment pathologist (second tier) reviews all lesions identified by the laboratory pathologist plus 10% of all remaining tissues. The reviews of the histopathology slides and final diagnoses of lesions in the RF radiation studies were made by pathology working groups (third tier involving over 30 pathologists). The latter reviews were conducted similarly to all other NTP studies in that the pathologists did not know whether the slides they were examining came from an exposed or an unexposed animal (Maronpot and Boorman 1982). In fact, the reviewing pathologists didn't even know that the test agent was RF radiation. The assertion by ICNIRP, which has never been made in the 40-y existence of the NTP, impugns the validity of all 600 bioassays performed by this program. However, for anyone questioning the diagnosis of any tissue in this study, unlike most other institutional studies, all of the slides from the NTP studies are available for examination at the NTP archives.

Rat survival rates

The ICNIRP note states "…that survival was lower and mortality faster in the male rat controls than in the exposed groups" and, therefore, "There remains a strong possibility that the decrease in survival resulted in underrepresentation of late-developing tumors in the controls that importantly affected the statistical results." However, as explained by Melnick (2019), this comment is an inaccurate portrayal and interpretation of the data for at least two reasons: (1) there was no statistical difference in survival between control male rats and the exposure group with the highest rate of gliomas and heart schwannomas (CDMA-exposed male rats, SAR = 6.0 W kg^{-1}), and until week 93 of the 2-y study, survival was greater in control male rats than in the 6 W kg^{-1} CDMA-exposed male rats [the mean survival for male rats in the 6 W kg^{-1} CDMA exposure group (637 d) was actually 5 d less than that for control male rats (642 d) (NTP 2018a)]; and (2) no glial cell hyperplasias (potential precancerous lesions that can progress to a malignant glioma) or heart schwannomas were observed in any control rat, even though glial cell hyperplasia was detected in exposed rats as early as week 58 of the 2-y study, and heart schwannoma

---

The author declares no conflicts of interest.

0017-9078/20/0

DOI: 10.1097/HP.0000000000001268

was detected as early as week 70 in exposed rats. Thus, survival was sufficient to detect tumors or pre-cancerous lesions in the brain and heart of control rats.

In their draft of this note that was posted last year (https://www.icnirp.org/cms/upload/publications/ICNIRPnote2018.pdf), ICNIRP cited a paper by Novilla et al. (1991) on the prevalence of spontaneous endocardial proliferative lesions in rats. The fact that Novilla et al. did not see either hyperplasias or schwannomas in 100 control male Sprague-Dawley rats lends further credibility to the absence of these lesions in the NTP study in Sprague-Dawley rats and supports the increased incidences of cardiac schwannomas being due to exposures to cell phone RF radiation. In addition, survival-adjusted overall primary tumor rates were greater in male rats exposed to GSM or CDMA RFR compared to concurrent control rats, with statistical significance observed in the 1.5 W kg^{-1} (CDMA) and in the 3.0 W kg^{-1} (GSM and CDMA) exposure groups (NTP 2018a; Lin 2019).

Multiple comparisons

Because of the large number of statistical comparisons, the ICNIRP note claims that by "…using a significance level of $p < 0.05$, many hundreds are expected to be significant by chance alone," and "It is therefore not possible to determine whether any of the results are due to RF-EMF exposure, as opposed to chance." This issue came up in the peer review of the NTP report of partial findings from the carcinogenesis studies of cell phone RF radiation (Wyde et al. 2016) and was addressed in the NTP's response to the reviewer's comments: "Although the NTP conducts statistical tests on multiple cancer endpoints in any given study, numerous authors have shown that the study-wide false positive rate does not greatly exceed 0.05 (Fears et al. 1977; Haseman 1983; Office of Science and Technology Policy 1985; Haseman 1990; Haseman and Elwell 1996; Lin and Rahman 1998; Rahman and Lin 2008; Kissling et al. 2014). One reason for this is that NTP's carcinogenicity decisions are not based solely on statistics. Many factors go into this determination, including whether there were pre-neoplastic lesions, whether there was a dose-response relationship, biological plausibility, background rates and variability of the tumor, etc. Additionally, with rare tumors especially, the actual false positive rate of each individual test is well below 0.05 due to the discrete nature of the data, so the cumulative false positive rate from many such tests is less than a person would expect by multiplying 0.05 by the number of tests conducted (Fears et al. 1977; Haseman 1983; Kissling et al. 2015)" (Wyde et al. 2016). Gliomas and heart schwannomas, which were found in the NTP studies on RF radiation, are uncommon tumors that occur rarely in control Sprague-Dawley rats.

Additional incorrect statements and misinformation in the ICNIRP critique that aim to undermine the utility of the NTP studies for assessing human health risks

1. One reason given by the ICNIRP Commission for dismissing the carcinogenic effects of RF-EMF in experimental animals is "...because there is currently no verified mechanism that would predict that RF EMFs would be carcinogenic." However, there is no requirement to establish a verified mechanism before accepting the carcinogenicity results of an agent in experimental studies. For most or perhaps all of the NTP studies that demonstrated carcinogenic activity, no verified mechanism had been identified when the studies had been completed. With respect to RF-EMF, Yakymenko et al. (2016) reported that evidence of oxidative stress was observed in 93 of 100 studies dealing with oxidative effects of low intensity RF radiation. Furthermore, oxidative stress can lead to mutations, chromosomal translocations, and genetic instability (Smith et al. 2016), and DNA damage was observed in brains of rats and mice exposed to RF radiation in the NTP studies (NTP 2018a and b; Smith-Roe et al. 2019). Oxidative stress caused by EMFs is thought to be due to the altering of recombination rates of short-lived radical pairs leading to increases in free radical concentrations (Barnes and Greenebaum 2015). Thus, oxidative stress leading to DNA damage may be involved in the induction of tumors from exposure to RF radiation (Lai and Singh 1997).
2. The ICNIRP Commission claims that "none of the compared pathologies were specified a priori as primary end points." This is wrong; all of the endpoints in the NTP study were specified in the NTP Specifications for the Conduct of Studies to Evaluate the Toxic and Carcinogenic Potential of Chemical, Biological and Physical Agents in Laboratory Animals, and in the Statement of Work for the conduct of the studies on RF radiation prior to the start of these studies.
3. In their evaluation of the carcinogenic potential of RF-EMF, the ICNIRP note failed to recognize that focal hyperplasias (proliferative lesions) of glial cells in the brain and of Schwann cells in the heart are putative preneoplastic lesions that may progress to malignant glioma or to cardiac schwannoma, respectively. In fact, the term hyperplasia is not present in the ICNIRP note.
4. While the ICNIRP note focused on the carcinogenicity of RF-EMF from animal studies, it neglected to point out that other adverse effects were observed in the NTP studies, including reduced birth weights, DNA strand breaks in brain cells (which is supportive of the cancer findings), increased incidences of

proliferative lesions (tumors and hyperplasia) in the prostate gland, and exposure-related increases in the incidence of cardiomyopathy of the right ventricle in male and female rats. In addition, other studies have reported adverse effects on male and female reproduction and neurobehavioral effects resulting from exposure to low intensity non-ionizing radiation (Belpomme et al. 2018).

5. In their attempt to downplay the concordance between schwannomas observed in animal studies and in human studies on cell phone radiation, the ICNIRP Commission claimed that an increased incidence of vestibular schwannoma (also called acoustic neuroma) from mobile phone use was reported "mainly by one research group" (Hardell et al. 2005, 2013). This statement is wrong since the INTEPHONE Study group (2011) reported that the odds ratio (OR) for acoustic neuroma after ≥10 y of mobile phone use was 2.79 (95% confidence interval: 1.51-5.16) for ≥1,640 h of cumulative call time. In addition, there were significant increases in the incidence of acoustic neuroma for ≥10 y use and on the same side of the head as reported phone use among the North European countries that participated in the Interphone study (Lönn et al. 2005; Shoemaker et al. 2005). The fact that "malignant cardiac schwannomas are extremely rare tumors in humans" and have not been investigated in epidemiological studies of RF-EMF does not detract from the concordance in cell type affected in animals and humans. The NTP findings of significantly increased incidences and/or trends for gliomas and glial cell hyperplasias in the brain and schwannomas and Schwann cell hyperplasias in the heart of exposed male rats are most important because the IARC classified RFR as a "possible human carcinogen" based largely on increased risks of gliomas and acoustic neuromas (which are Schwann cell tumors on the acoustic nerve) among long-term users of cell phones.

The hypothetical argument raised by ICNIRP about the effect of one additional cardiac schwannoma in the control group on *p* values lacks scientific credibility; one must analyze the available data rather than insert arbitrary values to downplay the significance of a true response. As noted above, carcinogenicity evaluations by the NTP are not based solely on statistics; other factors such as the presence of preneoplastic lesions and the rarity of the tumor also impact the evaluation of carcinogenic activity.

6. The ICNIRP note claims that, "The exposure levels used in NTP would indeed have raised body core temperature substantially," which "would have put them [male rats] under greater metabolic stress due to their greater thermoregulatory requirements." The main reason for this claim is that the "NTP measured superficial temperature rather than the body core temperature." However, there is no evidence to support the claim of substantial elevation of core temperature or that the rats were under metabolic stress. The NTP study used subcutaneously implanted transponders to monitor the effects of RF exposure on core body temperature; this approach was chosen because Kort et al. (1998) had shown that temperature changes recorded by the subcutaneous transponders did not differ significantly from rectal temperature measurements in rats or mice. In addition, it is clear that animals tolerated the exposure levels used in the NTP study, as there were no significant effects on body temperature, body weights in the 2-y study, induction of tissue damage in the 28-d study, nor exposure-related clinical observations.

7. The ICNIRP note claims that the "NTP exposures are not directly relevant to those encountered in the community" because "the NTP exposure of 6 W kg^{-1} is therefore 3 times higher than the local exposure restriction and 75 times higher than the whole-body exposure restriction for the general public." While the exposure limit to RF radiation for the general population in the US and Europe is 0.08 W kg^{-1} averaged over the whole body, the localized exposure limit is 1.6 W kg^{-1} averaged over any 1 g of tissue in the US (FCC 1997) and 2 W kg^{-1} averaged over any 10 g of tissue in Europe; for occupational exposures, the limit is five times higher (0.4 W kg^{-1} for whole-body exposures in the US and Europe, and 8 W kg^{-1} and 10 W kg^{-1} for localized exposures in the US and in Europe, respectively) (FCC 1997; ICNIRP 1998). Thus, the whole-body exposure levels in the NTP study were 19 to 75 times higher than the FCC's and ICNIRP's whole-body exposure limit for the general population and only 3.8 to 15 times higher than the occupational whole-body exposure limit. Whole-body SAR, however, provides little information about organ-specific exposure levels (IARC 2013). When an individual uses a cell phone and holds it next to his or her head, body tissues located nearest to the cell phone antenna receive much higher exposures than parts of the body that are located distant from the antenna. Consequently, the localized exposure level is more important for understanding and assessing human health risks from cell phone RF radiation. When considering organ-specific risk (e.g., risk to the brain) from cell phone RF radiation, the important measure of potential human exposure is the local SAR value of 1.6 W kg^{-1} (US) or 2 W kg^{-1} (Europe). In the NTP study in which animals were exposed in

reverberation chambers to whole-body RF radiation at SARs of 1.5, 3, and 6.0 W kg^{-1}, exposures in the brain were within 10% of the whole-body exposure levels. Thus, with respect to dosimetry in the brain, the exposures in the brain were similar to or only slightly higher than the localized exposure limits set by the FCC and ICNIRP for the general population (1.6 and 2 W kg^{-1}, respectively), and lower than the localized limits for occupational exposures of 8 and 10 W kg^{-1} (FCC 1997; ICNIRP 1998). Consider the converse scenario. If the brain and whole-body exposures were limited to 0.08 W kg^{-1}, then localized exposures in humans from use of cell phones held next to the ear could be 20 to 25 times greater than exposures to the brain of rats in the NTP study. Under this condition, a negative study would not be informative for evaluating organ-specific human health risks associated with exposure to RF radiation. The ICNIRP statement, "Research using substantially lower exposure levels would be required in order to determine whether there was a risk to the public," is contradictory with methodologies used to assess population-based human cancer risk (US EPA 2005).

8. The NTP cancer study was 2 y in duration; animals were not exposed "over the whole of their lives." Surviving animals were killed at about 110 wk of age; e.g., more than 70% of mice were still alive at the end of the study (NTP 2018a and b).

CONCLUSION

ICNIRP's misrepresentation of the methodology and interpretation of the NTP studies on cell phone RF radiation does not support their conclusion that "limitations preclude drawing conclusions about carcinogenicity in relation to RF EMFs." In contrast to the ICNIRP evaluation, a 3-d independent peer-review of the NTP studies concluded that there was *clear evidence of carcinogenic activity* in male rats exposed to RF radiation (NTP 2018c). In addition, the dosimetry issue raised in the ICNIRP note falsely portrays the relevance and utility of the NTP cancer data for assessing human cancer risks. After all, it was the US Food and Drug Administration that requested the NTP studies of cell phone radiation in experimental animals to provide the basis to assess the risk to human health. The NTP studies show that the assumption that RF radiation is incapable of causing cancer or other adverse health effects other than by tissue heating is wrong. If ICNIRP's goal is truly aimed at protecting the public from potential harm, then it would be appropriate for this group to quantify the health risks associated with exposure to RF-EMFs and then develop health-protective guidelines for chronic exposures, especially for children, who are likely to be more susceptible than adults to adverse effects of RF radiation. At the very least, ICNIRP should promote precautionary advice for the general public rather than trying to justify their decision to dismiss findings of adverse health effects caused by RF-EMFs and thereby retain their 20+ y-old exposure guidelines that are based on protection against thermal effects from acute exposures.

Acknowledgments—The author led the design of the NTP studies on cell phone RF radiation during his tenure in the NTP.

Running title:

OCCUPATIONAL EXPOSURE TO RF EMF

Abstract: High exposures to radiofrequency electromagnetic fields (RF EMF) are possible in workplaces involving sources used for broadcasting, telecommunication, security and identification, remote sensing and the heating and drying of goods. A systematic literature review of occupational RF EMF exposure measurements could help to clarify where more attention to occupational safety may be needed. This review identifies specific sources of occupational RF EMF exposure and compares the published maximum exposures to occupational exposure limits. A systematic search for peer-reviewed publications was conducted via PubMed and Scopus. Relevant grey literature was collected via web searches. For each publication, the highest measured electric field strength, magnetic flux density or power density was extracted. Maximum exposures exceeding the limits were reported for dielectric heating, scanners for security and radiofrequency identification, plasma devices and broadcasting and telecommunication transmitters. Occupational exposure exceeding the limits was rare for microwave heating and radar applications. Some publications concerned cases studies of occupational accidents followed by a medical investigation of thermal health effects. These were found for broadcasting antennas, radar installations and a microwave oven and often involved maintenance personnel. New sources of occupational exposure such as those in fifth generation telecommunication systems or energy transition will require further assessment.

Key words: Electromagnetic fields, Radiofrequency, Exposure, Occupational, Regulation

Introduction

Radiofrequency electric, magnetic and electromagnetic fields (RF EMF) with frequencies from 100 kHz to 300 GHz can be used to convey information (broadcasting, telecommunication, radiofrequency identification), for remote sensing (radar, security scans) for heating and drying of goods and for medical diagnostic or therapeutic purposes. If they are sufficiently strong, RF EMF can lead to excessive heating and tissue damage. Some of the strongest human-made sources of EMF can be found in the workplace. The International Commission for Non-Ionizing Radiation Protection (ICNIRP) has defined basic restrictions in terms of the specific absorption rate (SAR) and power density in the body, below which these health effects will not occur[1, 2)]. Reference levels in terms of the electric field strength, magnetic field strength or flux density and power density of the external fields outside the body have been derived from these basic restrictions. When workers are exposed to RF EMF weaker than the reference levels, the basic restrictions will not be exceeded under most circumstances, except for exposure of the limbs at frequencies between 100 kHz and 110 MHz. For this frequency range, separate reference levels were set for limb current, since exposure below the action levels for electric field strength does not guarantee that the SAR in the limbs, with their relatively small diameter, is not exceeded. The European Union (EU) has used the 1998 ICNIRP basic restrictions and reference levels to set legal limits for worker exposure to RF EMF in its occupational health and safety legislation by way of Directive 2013/35/EU (further called 'EU Directive'). In the EU Directive, the reference levels are called 'action levels' and the basic restrictions 'exposure limit values' (Table 1 and Table 2)[3)]. Although the original transposition deadline was 1 July 2016, due to delays in the legal process in some member states the EU directive had been implemented in all EU member states by August 2017[4)].

A systematic assessment of published studies on occupational RF EMF exposure could help to clarify where more attention to occupational safety may be needed. The European Commission has published a guide of good practice for the EU Directive, which tabulates working environments in which the action levels may be exceeded and further risk assessment is required[5)]. On the basis of the good practice guide and the results of a search with general RF EMF search terms (see 'methods' section), six categories of working environments were selected for review of occupational RF EMF exposure.

In the category of dielectric heating, a dielectric material (polarisable insulator) is placed in an alternating RF EMF between two electrodes, resulting in energy absorption without conduction and consequently heating. It is mainly used to deform, melt, weld or seal plastic materials[6)]. Frequencies for this application lie between 4 and 70 MHz, with a strong concentration in the 27 MHz band. The same physical principle is employed at higher frequencies (mainly at 915 MHz and 2.45 GHz) for microwave heating of food, wood and ceramics for purposes of drying, curing, shaping, sterilisation or pest control[7)]. In the category security and radiofrequency identification (RFID), RF EMF in the frequency bands around 100 kHz, 10 MHz, 1 GHz and 24 GHz are used for article detection and identification and for security scans of persons and objects[8)]. In industrial processes involving plasma etching, plasma sputtering and vapour deposition, RF EMF are used to apply thin layers of material to components in the electronics industry[9)]. In the category broadcasting and telecommunication, RF EMF are employed to convey radio and television signals and information for mobile communication and wireless data transfer by the general public and by industry, air and marine traffic control, the emergency services and the military. Frequency use ranges widely between 100 kHz and 300 GHz[10)]. Radar uses the reflection of RF EMF to determine the range, angle, velocity or composition of objects. It can be applied to detect and analyse the motion or composition of aircraft, missiles, ships, vehicles, weather formations, terrain and soil layers. Frequency bands vary according to application from 3 MHz to 110 GHz[11)].

The present review complements two earlier reviews using the same methodology. The most recent of these (2018) focused on low frequency and RF EMF sources that are exclusively used in medical, physiotherapy or dental practice[12)]. These sources of occupational exposure have therefore been excluded from the present review. Occupational exposure to low frequency magnetic fields was reviewed in 2014[13)], which included induction heaters with frequencies up to 1 MHz. Sources that are also used by the general population outside the workplace, such as mobile phones and other wireless consumer products, also fall outside the scope of the present review.

Methods

Data collection

A systematic literature search for peer-reviewed articles on occupational exposure to RF EMF published up to December 2020 was conducted in PubMed (http://www.ncbi.nlm.nih.gov/pubmed/) and Scopus (http://www.scopus.com/). Pagination of advance publications was added if available before submission of the manuscript. For a first general search, a combination of blocks of search terms were used, relating to RF EMF [((“radio frequ*” OR radiofrequ* OR rf OR microwave* OR “millimeter wave*” OR “millimetre wave*” OR “mm wave*” OR radar*) AND (field* OR radiat* OR wave*))], occupational setting [(worker* OR occupation* OR workplace OR employ* OR working OR “work floor”)] and exposure [(exposure OR dosimetry OR intensity OR “power densit*” OR “field strength*” OR “flux densit*” OR “specific absorption” OR sar)] but excluding frequencies in the range of optical radiation [(NOT (“optical radiation” OR ultraviolet OR uv OR infrared OR “visible light”)]. Secondly, searches for specific sources of occupational exposure to RF EMF were conducted in Pubmed and Scopus, using a combination of the search terms related to RF EMF and occupational setting (see above) with each of the following sets of source-specific search terms: [((dielectric* OR plastic) AND (heating OR heater* OR welding OR welder* OR sealing OR sealer* OR curing OR curer*))]; [(oven* OR drying OR dryer*)]; [(“article surveill*” OR antitheft* OR “anti theft*” OR security* OR rfid* OR “radiofrequency identification*”)]; [(telecom* OR radio OR television OR broadcast* OR tetra OR c2000) AND (mast* OR antenna* OR transmitter* OR station* OR beacon* OR tower*)]; [(radar*)]; [(military OR “armed forces” OR aircrew* OR soldier* OR sailor* OR army OR airforce* OR “air force*” OR navy)]; [(wireless AND “power transfer*”)]; [(plasma AND (etching OR sputtering OR stripping OR “vacuum deposition*” OR “surface treatment*”)]. In Scopus, document types such as conference abstracts that were not full journal articles were excluded, as well as subject categories not relevant for RF EMF exposure (SUBJAREA,

“MATE”; SUBBJAREA, “CHEM”; SUBJAREA, “CENG”; SUBJAREA, “EART”; SUBJAREA, “BUSI”; SUBJAREA, “ARTS”; SUBJAREA, “ECON”). For Pubmed, 1,879 results were found with the general search terms and 2,397 with the source-specific search terms (with an unknown overlap between the two). After screening of titles and, if necessary for clarification, abstracts, 89 articles were selected as potentially relevant, 31 of which were discarded after full-text screening for lack of suitable individual exposure values. For Scopus, 1,771 results were found with the general search terms and 3,662 with the source-specific search terms (with an unknown overlap between the two). After screening of titles and, if necessary for clarification, abstracts, 42 articles were selected as potentially relevant and were not also found with the Pubmed search, 27 of which were discarded after full-text screening for lack of suitable individual exposure values.

Relevant grey literature (measurement reports) in English, German, French or Dutch was identified on the websites of the following organisations: Agence nationale de securité sanitaire, alimentation, environnement, travail (ANSES) (France), Bundesamt für Strahlenschutz (Germany), Deutsche Gesetzliche Unfallversicherung (Germany), European Commission (Brussels), Health and Safety Executive (UK), Institut national de recherche et de sécurité (INRS) (France), Istituto Nazionale per l'Assicurazione contro gli Infortuni sul Lavoro (INAIL) (Italy), National Institute for Occupational Safety and Health (NIOSH) (USA), National Technical Reports Library (USA), Public Health England (UK), TNO (Netherlands), Vito (Belgium).

Data extraction

Only those publications listing individual maximum exposure values at specific frequencies were used, because frequency-averaged or group-averaged data make it impossible to compare maximum individual exposures to the action levels (reference levels) or exposure limit values (basic restrictions). Where the exposure was listed as a proportion of the action levels, the actual exposure was calculated by multiplying with the action level at the relevant frequency. Wherever possible, for frequencies below 10 GHz the 6-minute averaged values were used in accordance with the EU Directive and the underlying 1998 ICNIRP guidelines. Where only measurements in shorter time intervals were available, this is clearly mentioned as a caveat when comparing with the exposure limits. Where exposure was intermittent and the duty cycle was given, exposure values corrected for duty cycle were used. Where multiple publications were produced by the same authors, based on same subjects and study protocol, the maximum exposure values were extracted from only one of these publications. Apart from the distance to the source, worker exposure from radiofrequency devices also depends on the output power of the device in question (for example for dielectric heating equipment). It was assumed that the maximum exposures extracted are associated with the highest output power under normal working conditions. Where available, both maximum electric field and magnetic field measurement values were extracted for the same exposure since these may not always be coupled at the place of exposure. In accordance with the EU Directive, all magnetic field measurements are presented as magnetic flux density. Where only the magnetic field strength was available, the magnetic flux density was calculated by multiplying with the magnetic permeability ($4\pi \times 10^{-7}$ H/m). For radar exposure, where the (equivalent) frequency exceeded 6 GHz for a substantial proportion of measurements and energy deposition is limited to the outer layer of the body, the maximum equivalent plain wave power density was extracted for comparison with the exposure limits. In the minority of radar publications where only electric field strength was given at such frequencies, the power density was calculated using the formula: $S = E^2/Z$ with $Z = 377\ \Omega$. For lower frequencies and the minority of publications where only the maximum power density was given, this was converted to electric field strength for easier comparison, using the formula: $E = \sqrt{(S \times Z)}$ with $Z = 377\ \Omega$. For pulsed fields, such as those of some radar devices, the peak power density in the pulse was extracted where available and compared with the relevant action level (reference level) times 1,000 (for power density), as instructed in the EU Directive and underlying ICNIRP guidelines. Where peak values were measured or calculated, they have been converted to root-mean-square (rms) values by dividing by $\sqrt{2}$, for comparison with the action levels. Where no mention of peak or rms values was made in the publication, rms values were assumed. Exposure measurements were directly compared to action levels, without taking measurement uncertainty into account, since the source publication did not generally provide sufficient information on measurement uncertainty.

Exposure at the main frequency component with highest exposure was used, even though higher harmonics may also contribute to exposure. Where action levels are exceeded, this should be seen as an indication that there are potential issues with exposure levels for higher harmonics and that the frequency-summated exposure may be higher. The highest value of electric field strength, magnetic flux density or power density measured at the actual workplace was used as an indicator of maximum exposure to the source. When this was not available (usually when fields were measured at a standardised distances to the source), the highest value measured at distance that was possible with intended or foreseeable use was taken. When measurements were made at multiple heights from the floor, the height with the highest exposure was chosen. Not all publications contained sufficient information to determine whether the maximum measured values listed were restricted to the limbs. Where insufficient information was available it was presumed that all measured values may have involved head or trunk exposure. In the figures, a distinction is made between data points from publications before 2012 and data published from 2012 onwards, since it had become clear by then that the 2013 EU Directive would be applying legally binding exposure limits based on the 1998 ICNIRP guidelines.

For those publications in which the SAR or absorbed power density were calculated, these data are discussed in the text and related to the relevant exposure limit value (basic restriction). In some publications exposure was clearly due to an accident, where possible exposure above the limit values was suspected and an occupational medical investigation was conducted. Data from these publications are not included in the figures, but discussed separately in the text for each category of working environment.

Results

Dielectric heating (plastic welding)

A total of 25 publications had data on worker exposure near devices for dielectric heating to deform, melt, weld or seal plastic materials (3 of which published after 2011). Most of these investigations corrected for the fact that the apparatus was only active for part of the 6-minute averaging period ('duty cycle' smaller than 1), making the time-averaged exposure lower than that in the active period. The highest measured electric field strengths and magnetic flux densities to which workers could be exposed are shown in Fig. 1. The majority of these highest exposure values were above the action levels in the EU Directive for the electric as well as the magnetic field. In 2 publications with transgression of action levels the local and whole body averaged SAR was calculated[26, 31)]. In one of these, the situation with transgression of the action levels also resulted in a local SAR in the legs that exceeded the exposure limit value[26)]. In 3 out of the 7 publications where the limb current was measured, this could exceed the action level[27, 29, 35)]. In working environments where action levels are exceeded, EU Directive requires that the employer takes measures to reduce exposure, or demonstrates that the exposure limit values are not exceeded. Some publications investigated the effect of exposure reduction measures and showed that the field strength remained below the action levels after applying appropriate shielding to the device[16, 25, 36)].

Security and RFID

A total of 17 publications had data on worker exposure near devices for security scans or RFID (6 of which published after 2011). These concerned measurements of (potential) workplaces near gates or hand-held scanners for the detection or deactivation of anti-theft labels in shops, security scanners in public buildings including airports and scanners for the identification of objects via RFID (e.g., access passes, goods). The highest measured field strengths and magnetic flux densities to which workers could be exposed are shown in Fig. 2. For body scanners using millimetre waves (frequencies around 2.4 GHz) the field strength was always lower than the action levels and the calculated SAR was below the exposure limit values[45, 46)]. For anti-theft gates and RFID-scanners, which use RF EMF with frequencies around 100 kHz and 10 MHz, the majority of maximum exposure values was higher than the action levels, both for publications before and after 2012. However, an important caveat is that the exposure was not averaged over 6 minutes in these publications and the realistic exposure duration was not investigated. In 6 publications the local and whole body averaged SAR were calulated[40, 45–48, 51)]. One of these showed a whole body averaged SAR higher than the exposure limit value, if exposure lasted longer than 6 minutes[48)]. Contact currents were reported in 1 publication, but these did not exceed the action level[40)].

Plasma devices

A total of 3 publications had data on worker exposure near equipment for radiofrequency industrial surface treatments, including plasma etching, plasma sputtering and vacuum deposition (2 of which published after 2011) (Fig. 3). Action levels were exceeded near (closer than 10 cm to) a device for plasma sputtering operating at 13.6 MHz[40] and near a microwave generator used for plasma excitation operating at 2.3 GHz[54]. If exposure would last sufficiently shorter than 6 minutes or if a greater distance could be observed, exposure would be expected to remain under the action levels. In 1 publication contact currents were measured, which exceeded the action level with a device for plasma sputtering (both touch and grasp contact), but not with a device for plasma-etching[40].

Broadcasting and telecommunication

A total of 31 publications had data on worker exposure in working environments near broadcasting antennas (radio and television) or antennas or professional user devices for mobile telecommunication (telecom operators, company mobile radio, emergency services, armed forces), 14 of which were published after 2011. Maximum occupational exposure exceeding the action levels occurred more frequently for broadcasting antennas than for telecommunication antennas and in most cases was found in publications before 2012 (Fig. 4). The majority of publications assumed that exposure could last at least 6 minutes, but it was not usually reported how likely that was to happen in normal work activities. In 2 publications concerning workers near an FM antenna the SAR was calculated where the action levels were exceeded and was found to exceed the exposure limit value for the whole body[73, 81]. In 5 publications concerning networks for the emergency services, the local SAR exposure limit value for handsets or vehicle antennas was not exceeded[66, 67, 82–84]. The local head SAR was exceeded during maintenance work on an unscreened portaphone transmitter[58]. Limb current was measured and exceeded the action level in 1 publication for medium frequency (1.3 MHz) and high frequency (6 MHz) transmitters, but in both cases the action levels for electric field strength were also exceeded[63]. Contact currents were reported in 1 publication (military high frequency antenna), but these did not exceed the action level[64]. Three publications (not shown in graph) concerned an accident (incident where overexposure was suspected), followed by a medical examination. In the first of these, the exposure of maintenance personnel near a broadcasting antenna proved to be lower than the action levels[85)]. In a second case study, a maintenance lift got stuck in front of a broadcasting antenna, where the exposure was 4 times the action level for 2.5 minutes. Registered symptoms were an acute feeling of warmth and skin redness, headache, diarrhoea, malaise and paresthesia which lasted several days after the incident[86)]. A second publication by the same author reported similar symptoms in case studies of antenna engineers working near broadcasting antennas for extended periods, where action levels could have been exceeded[87)].

Microwave drying and heating

A total of 5 publications had data on worker exposure near devices for drying, curing or heat sterilisation of goods (1 published after 2011). Four of these used microwave frequencies (2.5 GHz) and showed that the maximum power density at the workplace was lower than the action level (Fig. 5). One publication showed exposure higher than the action level for one of the two devices investigated, but this concerned an oven where the shielding door had a defect[88)]. One publication concerned radiofrequency textile driers operating at 27 MHz, where electric field strength and magnetic flux density immediately next to the opening could exceed the action levels five-fold, presuming an exposure of at least 6 minutes[91)]. One publication concerned an accident (incident where overexposure was suspected), followed by a medical examination. A maintenance worker repairing microwave ovens (2.5 GHz) with interrupted interlock protection was exposed to a power density of four times the action level, on repeated occasions with a duration of at least 4 minutes. Symptoms were a feeling of warmth, skin redness and a burning sensation in the eyes[92)].

Radar

A total of 20 publications had data on worker exposure in working environments involving radar installations for identification and analysis of aircraft, missiles, shipping, cloud formations or for road speed detection. Five of these were published after 2011 and 6 publications concerned military installations. When determining exposure, the fact was taken into account that for certain radar applications the bundle moves or rotates and exposure only occurs part of the time (‘duty cycle’). In the majority of publications, exposure was lower than the power density action levels (Fig. 6). Exposure exceeding the action levels was reported in 2 publications. The first of these concerned a police officer located in the bundle of a speed detector, which may be considered as unintended use[100)]. The second concerned the operator of a military target radar[101)]. For pulsed radar, apart from the time-averaged exposure, the peak exposure in the pulses is important. The reference level for power density for peak exposure in the pulse is 1,000 times the reference level for time-averaged exposure[1, 3)]. For the 3 publications in which the peak exposure in the pulse was given (air traffic and shipping radar), this was lower than 1,000 times the action level[53, 103, 104)]. Five publications (not shown in graph) concerned an accident (incident where overexposure was suspected), followed by a medical examination. All of these involved military radar applications: 3 publications with exposure of maintenance personnel (1.5 to 3 times the action level)[106–108)] and 2 publications with onboard exposure of navy personnel to RF EMF from a target location radar (4 times the action level)[109)] or the area radar of a closely passing ship (10 times the action level)[110)]. In the latter case, the action levels for peak exposure in the pulse and the exposure limit value for whole body SAR were also exceeded. Recorded symptoms varied from psychological stress to a feeling of warmth, malaise, pain, dizziness, nausea or irritated eyes.

Other sources

One publication was found which assessed occupational RF EMF in a scientific laboratory (nuclear facility). Electric field strength near a pump source for laser radiation (5 MHz) and near an RF quadrupole accelerator (55 MHz) were in the order of 1% of the action levels[111)]. The publications that were found on the strength of RF EMF associated with wireless power transfer did not specifically concern occupational exposure.

Discussion

The results of this systematic literature review show that the action levels and exposure limit values for RF EMF in the EU Directive (derived from the 1998 ICNIRP guidelines) can be exceeded, in varying proportions, for maximum exposures in working environments involving dielectric heating of plastic materials, security or RFID scanners, plasma devices, broadcasting and telecommunication, but only rarely for microwave drying or heating and radar.

For plastic welding using RF EMF-induced dielectric heating, the majority of highest exposure values registered exceeded the action levels. Since these publications usually took account of time-averaging and duty cycle, the possibility of overexposure is realistic in these cases and exposure reduction measures would be in order. The alternative is to calculate whether the SAR basic restrictions are not exceeded, but this is normally unrealistic for employers since the necessary calculations and computer simulations can be generally only be performed by experts in numerical dosimetry[112)]. A similar potential for maximal exposures exceeding the action levels occurs with textile or glue dryers which operate in the same ('diathermy') frequency band of 27 MHz[91)]. The available literature seems to indicate that there is less potential for overexposure for microwave drying, curing or sterilisation, provided that shielding doors are in good working order. Exposure reduction for plastic welding or other industrial applications of diathermy can involve the application of shielding or replacement with new equipment with more effective shielding, the removal of reflecting objects near the workplace, effective grounding and proper maintenance[16, 25, 36)].

For security and RFID-scanners, the majority of publications reported instantaneous maximum exposure levels higher than the action levels. However, the 6-minute averaged exposure can still remain under the action levels if the exposure duration is short enough. One would expect that this would usually be the case, unless the worker lingers next to a security gate for longer periods of time. The simplest control measures here would be increasing the distance to the scanner and limiting the time near the scanner when close approach is deemed necessary. For full body scanners using millimetre waves, overexposure is not an issue, even if workers are scanned themselves for security reasons.

For radiofrequency plasma devices, it is possible that action levels are exceeded close to the source, but again this presupposes that the worker’s exposure lasts 6 minutes or longer. Ineffective shielding (panelling or casing) may be a source of avoidable high exposure for plasma devices. In an extreme case, when maintenance is performed on an active device by a worker inside the protective panelling, the exposure close to the device can be 10 times the action level[53)]. This underlines the need to pay special attention to maintenance workers in risk assessments for occupational RF EMF exposure.

For broadcasting and telecommunication antennas, there was evidence that the maximum exposures could exceed the action levels and exposure limit values near the antenna installation, again assuming that they would last at least 6 minutes. Unlike publications before 2012, the majority of publications after 2011 gave maximum occupational exposures lower than the action levels, although higher exposures could still occur for both broadcasting and telecommunication antennas. This may indicate increasing awareness of the legal exposure limits, coupled to the technical know-how on monitoring worker exposure in the broadcasting and telecommunication sector. Local SAR from handsets specific for the working environment under normal use (company networks, emergency services, armed forces) did not exceed the exposure limit values. The only exposure exceeding the local SAR was found for maintenance work on an unscreened portaphone older than 1991, again underlining the potential for higher exposure of maintenance personnel[58)]. The three case studies on overexposure accidents at antenna sites associated with a medical examination also concerned personnel performing maintenance work[85–87)].

For radar, the vast majority of published maximum workplace exposures under normal working conditions was lower than the action levels. Of the three publications which found an exposure higher than the action levels, one concerned a mechanic at an aircraft manufacturer (‘maintenance’)[103)], one a military radar operator[101)] and one a policeman in the beam of a traffic scanner[100)], which could be considered unintended use. In the latter publication, only 0.4% of all workplace measurements performed exceeded the action levels. The five accidental overexposure incidents with medical examinations all concerned military radar systems. Three of them involved maintenance personnel[106–108)] and the two remaining case studies concerned navy personnel accidentally exposed to radar beams from target locators[109)] or from a closely passing ship[110)]. Only one publication was found on the varied RF EMF exposures that can occur in the setting of research laboratories. More attention to these potentially diverse working environments may be warranted.

As discussed in the preceding reviews[12, 13], the approach to reviewing maximum exposures with regard to exposure limits has several limitations. Only the maximum exposures at the workplace per frequency per publication are listed as an indication of worst-case conditions. They were usually performed at a fixed height and did not take account of spatial averaging, giving a conservative estimate of exposure[5]. These maximum exposures are not necessarily representative of the majority of exposures and may not always represent good working practice. For dielectric heating (e.g., plastic welding) in particular, most of the literature database is older than 2012, and it may be that more recent devices in combination with mitigation measures have reduced the potential for worker overexposure. On the other hand, it cannot be excluded that even higher exposures are possible in working environments or scenarios that are not covered by the publications reviewed here. A comparison with the limits in the EU Directive was only made for the main frequency of the source in question. Other frequency components may add to the total exposure and multiple RF EMF sources in the same workplace also need to be added to total exposure. When comparing exposure measurements to legal limits, measurement uncertainty needs to be taken into account[5], but source publications in the present review did not generally provide sufficient information to assess the impact of measurement uncertainty.

The technology of sources of occupational RF EMF exposure continues to evolve. Exposure guidelines and regulation likewise need to evolve to incorporate these developments, as do the techniques used to assess occupational exposure. One example of such developments are the new applications that are becoming available in the fifth generation of mobile telecommunication systems (5G). The higher frequencies and more superficial energy deposition, the use of beam forming, the more widespread use of small cells and local networks for machine-to-machine communication and the use of ultra-wideband pulsed fields do not necessarily create higher exposures, but do make exposure assessments more complicated[113, 114]. Apart from some limited adjustment of reference levels and averaging times, the most recent ICNIRP guidelines for RF EMF introduce new limits for brief, localised exposure at frequencies from 400 MHz to 300 GHz, which are relevant in this context[2]. It should be investigated whether these limits for brief, localised exposures raise new compliance issues for the types of working environments discussed in this review. Another example of novel types of exposure is the increased use of wireless power transfer, for example in charging electric vehicles such as busses and trucks, which generally uses RF EMF in the frequency range from 100 kHz to 50 MHz[115]. Publications in recent years indicate that nearby exposure is lower than the action levels, but these assessments were not specific for occupational exposure[116, 117]. Further investigation of occupational exposure scenarios would be useful.

Table 1. Exposure limit values for thermal effects in Directive 2013/35/EU

Frequency	Health effects ELV SAR (W/kg)	Health effects ELV power density (W/m^2)
100 kHz ≤ f < 6 GHz		
whole body average	0.4	–
localised 10 g, head and trunk	10	–
localised 10 g, limbs	20	–
6 GHz ≤ f < 300 GHz	–	50

Abbreviations: ELV, exposure limit value; SAR, specific absorption rate.

Note 1: Averaging mass for maximum localised SAR is any 10 g of contiguous tissue with roughly homogeneous electrical properties. Note 2: Power density shall be averaged over any 20 cm^2 of exposed area. Spatial maximum power densities averaged over 1 cm^2 should not exceed 20 times the value of 50 W/m^2. Power densities from 6 to 10 GHz are to be averaged over any six-minute period. Above 10 GHz, the power density shall be averaged over any $68/f^{1,05}$ -minute period (where f is the frequency in GHz).

Table 2. Action levels for thermal effects in Directive 2013/35/EU

Frequency	AL electric field strength (V/m)	AL magnetic flux density (μT)	AL power density (W/m^2)
100 kHz $\leq f <$ 1 MHz	6.1×10^2	$2.0\times10^6/f$	–
$1 \leq f <$ 10 MHz	$6.1\times10^2/f$	$2.0\times10^6/f$	–
$10 \leq f <$ 400 MHz	61	0.2	–
400 MHz $\leq f <$ 2 GHz	$3\times10^{-3}\sqrt{f}$	$1.0\times10^{-5}\sqrt{f}$	–
$2 \leq f <$ 6 GHz	1.4×10^2	4.5×10^{-1}	–
$6 \leq f <$ 300 GHz	1.4×10^2	4.5×10^{-1}	50

Abbreviations: AL, action level.

Note 1: f is the frequency in hertz (Hz). Note 2: Squared AL for electric field strength or magnetic flux density are to be averaged over a six-minute period. For RF pulses, the peak power density averaged over the pulse width shall not exceed 1,000 times the respective AL value. For multi-frequency fields, the analysis shall be based on summation, as explained in the practical guides referred to in Article 14 of the EU Directive. Note 3: AL for electric field strength or magnetic flux density represent maximum calculated or measured values at the workers' body position. In specific non-uniform conditions, criteria for the spatial averaging of measured fields based on established dosimetry will be laid down in the practical guides referred to in Article 14 of the EU Directive. In the case of a very localised source within a distance of a few centimetres from the body, compliance with ELVs shall be determined dosimetrically, case by case. Note 4: Power density shall be averaged over any 20 cm^2 of exposed area. Spatial maximum power densities averaged over 1 cm^2 should not exceed 20 times the value of 50 W/m^2. Power densities from 6 to 10 GHz are to be averaged over any six-minute period. Above 10 GHz, the power density shall be averaged over any $68/f^{1,05}$ -minute period (where f is the frequency in GHz).

Manmade Electromagnetic Fields and Oxidative Stress—Biological Effects and Consequences for Health

David Schuermann [1,*] and Meike Mevissen [2,*]

1 Department of Biomedicine, University of Basel, Mattenstrasse 28, CH-4058 Basel, Switzerland

Abstract: Concomitant with the ever-expanding use of electrical appliances and mobile communication systems, public and occupational exposure to electromagnetic fields (EMF) in the extremely-low-frequency and radiofrequency range has become a widely debated environmental risk factor for health. Radiofrequency (RF) EMF and extremely-low-frequency (ELF) MF have been classified as possibly carcinogenic to humans (Group 2B) by the International Agency for Research on Cancer (IARC). The production of reactive oxygen species (ROS), potentially leading to cellular or systemic oxidative stress, was frequently found to be influenced by EMF exposure in animals and cells. In this review, we summarize key experimental findings on oxidative stress related to EMF exposure from animal and cell studies of the last decade. The observations are discussed in the context of molecular mechanisms and functionalities relevant to health such as neurological function, genome stability, immune response, and reproduction. Most animal and many cell studies showed increased oxidative stress caused by RF-EMF and ELF-MF. In order to estimate the risk for human health by manmade exposure, experimental studies in humans and epidemiological studies need to be considered as well.

Keywords: oxidative stress; ROS; electromagnetic field; extremely low frequency; radiofrequency; environment and public health; environmental exposure; animal study; cultured cells

1. Introduction

Reactive oxygen species (ROS), as well as related reactive nitrogen species (RNS), are involved in many biological processes; nonetheless, they pose a hazard to the biological material and physiology of cells [1–3]. Protective mechanisms, such as antioxidants and antioxidative enzymes, maintain physiological concentrations of ROS in cells, while external and internal stimuli affect the amount of ROS by altering the activity of involved ROS-forming and -degrading enzymes [4]. For example, an increased energy requirement during physical activity leads to a temporary state of oxidative stress, and many environmental risk factors such as ionizing radiation in ultraviolet (UV) light or the radioactivity spectrum partly act via the formation of ROS. Pathophysiological levels of ROS interfere with many vital cellular processes and functions, such as inflammation, cell proliferation and differentiation, wound healing, neuronal activity, reproduction, and behavior by altering biochemical and signaling processes or even resulting in oxidative damage to DNA, RNA, and proteins or to the peroxidation of fatty acids [5,6]. If this unfavorable state persists over a long period or occurs repeatedly, it can lead to changes in the biological material, as well as the genetic and epigenetic information, and it can lead to health-related malfunctions. Accordingly, altered ROS levels and changes in biomarkers of oxidative stress as cause or consequence have been observed in many diseases, such as cancer, diabetes, congenital malformations, or neurodegenerative syndromes [1,3].

The influence of electromagnetic fields (EMF), as a manmade environmental factor with increasing importance, on ROS formation, triggering oxidative stress, has been repeatedly discussed. Corresponding hypotheses and experimental findings have been summarized and discussed in previous reviews on this topic [7–16]. Although there is consistent evidence for EMF-induced ROS formation in experimental studies, a complete picture and a scientific consensus have not yet emerged with regard to epidemiological association and possible negative and long-term consequences for health.

In this review, recently published relevant animal and cell studies were identified and evaluated with the aim toward providing an updated assessment of a causality between oxidative stress and exposure to magnetic and electromagnetic fields and their possible effects on health. The focus was put on environmentally and technologically relevant frequency ranges: extremely-low-frequency magnetic fields (ELF-MF) typical for 50/60 Hz alternating current (AC) power lines and radiofrequency electromagnetic fields (RF-EMF) in the frequency range from 800 MHz to 2.5 GHz as used for current mobile communication systems. This primarily involved experimental studies in animals and cultured and/or primary cells published in the peer-reviewed literature from 2010–2020 (Supplementary Materials, Tables S1–S4). These studies provided data about the influence of exposure on the formation of ROS, markers of oxidative stress, and changes in protective mechanisms that counteract oxidative stress.

Some studies are purely descriptive or contain mechanistic aspects that specifically track and investigate correlations and influenced processes. In animal experimentations, the balance of ROS and the antioxidant counterparts in the whole organism can be studied. In addition, functional changes, which are mostly based on a permanent imbalance and are, therefore, important for health, can be evaluated in animal studies. In addition to investigations on biomarkers of oxidative stress, molecular, morphological, or functional changes, such as induced DNA damage, impaired learning and memory, organ abnormalities, and decreased sperm count or motility are more conclusive for estimating possible adverse health effects. Therefore, studies showing functional changes are considered particularly important for estimating the impact of EMF on human health.

In the following chapters, we summarize important findings from animal and cell studies on oxidative stress and EMF exposure by organ system and related cell types, and we assess their relevance for human health. Furthermore, general aspects are included, which are independent of cell type and/or organ/tissue but need to be considered for such an assessment.

For this narrative review, a subset of animal and cell studies published in the last 10 years in English language that were considered relevant for the research question were assessed and included, in order to provide an overview of the current research. The included studies were extracted from databases available at BERENIS (https://www.bafu.admin.ch/bafu/en/home/topics/electrosmog/newsletter-of-the-swiss-expert-group-on-electromagnetic-fields-a/beratende-expertengruppe-nis-berenis.html, accessed on 10 June 2020), EMF Portal (https://www.emf-portal.org/en, accessed on 25 June 2020), and PubMed (https://pubmed.ncbi.nlm.nih.gov, accessed on 30 June 2020).

2. Background Information on Oxidative Stress

The chemical processes of oxidation and reduction are the basis for all biochemical reactions that make biological actions and life possible. The relatively reactive molecular oxygen in our atmosphere plays a central role in the production of energy from sunlight, as well as in the conversion of this energy by cellular respiration in the mitochondria, making it available for other biological processes. It is important for the function of cells and organisms that the reducing and oxidizing molecules are roughly in balance. This is known as redox balance. It is referred to as oxidative stress if this balance is disturbed, usually by an increase in oxidative processes [2,3]. The oxidative state is controlled and maintained by the cell's own sensors, signaling pathways, and defense mechanisms, in which the transcriptional regulation of many antioxidative and cytoprotective enzymes by the NRF2–KEAP1 system, consisting of the redox state-sensing Kelch-like ECH-associated protein 1 (KEAP1) and the transcription factor nuclear factor erythroid 2 related factor 2 (NRF2), plays a central role [17,18].

2.1. Origin of ROS and Oxidative Stress

Oxidative stress occurs primarily when the amount of reactive oxygen species (ROS) exceeds the neutralization capacity. In addition to the superoxide ($\bullet O_2^-$) and hydroxyl ($\bullet$OH) radicals, these include hydrogen peroxide (H_2O_2) and singlet oxygen ($^1O_2$), as well as organic compounds [2,3]. A major source of ROS is the mitochondria, which are present in every cell and play a central role in the energy supply. ROS are formed during metabolic processes of the mitochondrial electron transport chain ("respiratory chain"), in particular the superoxide anion radical $\bullet O_2^-$, H_2O_2, and the hydroxyl radical $\bullet$OH. It is estimated that, in the mitochondrial respiratory chain, about 2% of the oxygen consumed is not converted to water but to superoxide radicals. Persistent oxidative stress may lead to the destruction of mitochondria, microfilaments, and proteins, which lose their function through oxidation, resulting eventually in an impairment of their function in metabolic processes.

Other important sources of ROS include the nicotinamide adenine dinucleotide phosphate (NADPH) oxidases (NOX) and metabolic processes involving, for example, heme-containing cytochromes such as detoxifying enzyme cytochrome P450 [1,3,4,19]. NOX enzyme complexes consist of several subunits and occur in several forms in different cell types [20]. They produce the superoxide radical from molecular oxygen, which, depending on the cell type or organ, is used not only to defend against pathogens but also as a signaling molecule. Accordingly, the NADPH oxidases are either located at cell membranes or at the membranes of specific organelles (phagosomes) of macrophages, neutrophil granulocytes, and dendritic cells of the immune system, where trapped microorganisms are killed [21].

In immune cells, as well as in many other cell types, reactive nitrogen-containing molecules, the gaseous free radical nitric oxide ($\bullet$NO), play a role in addition to ROS. This is produced by three types of ubiquitously expressed nitric oxide synthases (NOS), which exist as endothelial (eNOS), neuronal (nNOS), and inducible (iNOS) isoforms [1,2]. While eNOS and nNOS are calcium/calmodulin-regulated enzymes, iNOS represents a cytokine-inducible form, which leads to a strong nitric oxide (NO) synthesis in immune cells (macrophage and microglia cells), as well as in other cell types, and it is involved in immune processes and controlled cell death. NO itself is an important messenger substance that, for instance, is involved in the regulation of blood circulation by vasodilation, neuronal functions, and immune defense. While it is not cytotoxic per se at normal concentrations, NO can react spontaneously with superoxide to form highly reactive peroxynitrite, which can damage the DNA and proteins, while it is also used in macrophages, for example, to defend against infections. In addition to the Fenton chemistry pathways, the peroxynitrite pathway poses a major oxidative stress-related threat to biological material.

Superoxide radicals can be converted to hydrogen peroxide (H_2O_2) by superoxide dismutases (SODs). This family of enzymes is, thus, the first antioxidative line of defense to control the superoxide radical ($\bullet O_2^-$), a byproduct of oxygen metabolism or specifically produced in immune cells by NADPH oxidases [22]. With the participation of metal ions, they convert superoxide radicals to the less reactive H_2O_2. Superoxide dismutases occur in different variants in most living organisms and cell types and act in the cytoplasm, in the mitochondria, and in the extracellular space.

2.2. Protective Mechanisms

Although these reactive molecules can potentially cause damage to biological material and impede functionality, their presence and production should not generally be considered harmful. As indicated in some examples in the previous chapter, they are even indispensable for some biological functions and mechanisms [1,2,19,23]. For example, $\bullet$NO and H_2O_2 are not only involved in the immune response, but also play a central role in the regulation of the redox state. H_2O_2 is also required for wound-healing processes or the correct formation of protein structures. It is important for the organism to keep ROS concentrations at a tolerable level, which is achieved through the cooperative action of antioxidants and enzymatic protection mechanisms, controlled by the NRF2–KEAP1 pathway, the key regulator of oxidative state and xenobiotic detoxification [17,18]. For example, provitamin A, vitamins C and E, and glutathione (GSH) act as antioxidants.

In addition, a number of enzymes play essential roles in controlling ROS. Peroxidases are able to process different forms of reactive peroxides, with H_2O_2 and lipid peroxides being the most relevant biologically in mammals. Different strategies and cofactors are used to neutralize these radicals by the addition of electrons. The peroxidase named catalase (CAT) plays a key role in the antioxidative defense system of many living organisms. It breaks down H_2O_2 to water and oxygen and, thus, neutralizes it [1,3]. CAT occurs in virtually all cell types and fulfils its function in specialized cell organelles, the peroxisomes, or in the cytoplasm and mitochondria. Peroxiredoxins (PRDx) also degrade H_2O_2, as well as organic peroxides [24]. Among other functions, for example, they regulate the cytokine-mediated signaling cascades and occur as antioxidant enzymes in mitochondria and in red blood cells. Glutathione peroxidases (GPx) and the GSH system are also vital. In humans and mammals, several types of glutathione peroxidases with preferences for either lipid peroxides or H_2O_2 have been identified [25]. The variants of GPx occur in specific cell types, as well as extracellularly or in the plasma. These enzymes can remove peroxides in a multistep process, converting reduced GSH into oxidized glutathione disulfide (GSSG). By the action of the glutathione reductase (GR), GSSG is then converted back to GSH, which is the predominant form of glutathione and an important antioxidant under physiological conditions.

2.3. Detection of Oxidative Stress

Intracellular ROS concentrations depend on the balance between ROS generation and its elimination. In general, fluctuations in ROS production and the rapid response of the related protective mechanisms can be measured. Several experimental approaches have been described to detect ROS generation, with dyes turning fluorescent upon contact with ROS being the one that is most commonly used [26]. However, it has to be noted that specificity and sensitivity for a particular ROS species are limited, depending on the method and compound applied. The activity or amount of superoxide dismutases (SODs), catalases (CATs), or peroxidases can also be used as an indicator of oxidative stress. An important and frequently used biomarker for oxidative stress is the availability of GSH or, rather, the ratio of reduced to oxidized glutathione (GSH/GSSG). The activity of glutathione reductase also provides information on the redox state.

In addition to direct measurements of ROS production and the antioxidative defense process, damage to biomolecules or their degradation products can be detected, especially as indicators for sustained oxidative stress. An increase in oxidized bases in the DNA (i.e., 8-oxo-G/8-OHdG) and the carbonylation of proteins serve as surrogate markers for ROS. Malondialdehyde (MDA), a degradation product of unsaturated fatty acids, is also a frequently analyzed biomarker for oxidative stress [27]. Malondialdehyde is formed during normal enzymatic reactions, as well as by ROS-induced peroxidation of membrane lipids (lipid peroxidation). MDA itself is highly reactive and can lead to structural changes and damage to DNA and proteins. Elevated MDA levels are observed in many chronic diseases, and such pathological levels may contribute to a variety of long-term health impairments.

3. Impact of EMF on the Nervous System

Due to their longevity and limited renewal, neurons are considered particularly sensitive to oxidative stress. Oxidative stress caused by chronic inflammation may result in substantial cell damage. Thus, ROS formation and consistent oxidative stress have been associated with neurodegenerative diseases and aging [1,20,23], whereby—among many other factors and environmental influences—an involvement of EMF-induced oxidative stress is conceivable. On the other hand, many aspects of neuronal development, plasticity, and signal processing rely fundamentally on the formation of ROS to establish and ensure normal functionality [19,23,28]. Thus, temporal changes of ROS formation in brain cells do not necessarily have to result in negative and health-relevant effects.

3.1. Observations in EMF-Exposed Animals

After short- or long-time EMF exposure, ROS production and the related antioxidant defense systems have mostly been investigated in laboratory animals, namely rats and mice (Supplementary Materials, Tables S1 and S3). In addition to the basic question of whether EMF exposure causes oxidative stress, in some cases, information about its transient or permanent nature, requiring ROS measurements in several animal groups with different exposure durations, provided additional data with respect to health impact. However, well-founded conclusions on health impact are only possible if additional functional investigations, such as learning behavior or the occurrence of DNA damage, are also measured. Small group sizes, from five animals upward, are considered meaningful studies with experimental animals.

In the last decade, about 50 original studies in laboratory animals have been published on EMF exposure and oxidative stress in the brain. In a comprehensive work with Sprague-Dawley rats, increased ROS activity or formation of MDA, 8-OHdG, and serum nitrite was observed after 6 months of RF-EMF exposure at different frequencies (900, 1800, and 2100 MHz) for 2 h per day [29]. The whole-body specific absorption rate (SAR) of 0.174–0.638 W/kg was below the existing regulatory limits and recommendations. Concurrently, indications for increased DNA damage were found in the brain, which correlated with the applied frequency but was only significantly different from the sham controls at 2100 MHz. At the same time, the capacity of the antioxidative protection system was exhausted as the measured antioxidative markers were significantly lower compared to sham-exposed animals [29]. These results indicate that oxidative stress induced by RF-EMF can lead to DNA damage in neurons during prolonged exposure of the animals. Virtually identical results were also found in several other studies [30–34]. In the study by Megha et al., Fischer-344 rats were exposed to RF-EMF with frequencies of 900, 1800, and 2450 MHz at whole-body SAR values of 0.59, 0.58, and 0.66 mW/kg, respectively, for 60 days (2 h/day and 5 days/week) [32]. Biomarkers for oxidative stress (including MDA) and various inflammatory markers were augmented correlating with the increasing frequency, while the antioxidative activity (SOD, GSH) decreased [32]. Similar observations were reported by Sahin et al., who measured increased ROS production in the brain of Wistar rats after universal mobile telecommunications system/third generation (UMTS/3G)-modulated RF-EMF exposure (2100 MHz, whole-body SAR: 0.4 W/kg; 6 h/day and 5 days/week) [33]. However, this ROS increase occurred only after 10 but not after 40 days of exposure, correlating with DNA damage but decreased lipid peroxidation in brain cells [33]. The absence of DNA damage after 40 days may indicate adaptation to exposure or enhanced capacity of DNA repair. Evidence for adaptation to or recovery from induced oxidative stress by 900 MHz RF-EMF (2.5 mW/cm^2, 1 h/day) was also observed in male Sprague-Dawley rats. ROS levels were elevated in the brain after 60 days of irradiation. However, ROS levels were not different from controls after a regeneration phase of 30 days without irradiation [35]. Correlating with exposure duration, changed levels of DNA damage were also found in hippocampal cells after 900 MHz RF-EMF exposure [34]. RF-EMF exposure for 90 days (1–4 h/day, 5 days/week at 0.231 W/kg) increased ROS formation, reduced antioxidative markers (SOD and CAT), and induced the formation of inflammatory cytokines. In addition, neuronal cell degeneration and other morphological changes in the brain were observed [34]. In contrast, an increase in oxidative stress was induced by RF-EMF exposure without affecting DNA damage levels in some other studies [36–39].

Adding to the studies with functional aspects, descriptive studies including analyses of ROS with and without measurements of antioxidative biomarkers were also published. With respect to health effects, they are less conclusive, especially if no data are available on whether the observed effects are temporary or persistent. Nevertheless, most of the studies indicate changes in ROS formation and/or oxidative stress biomarkers [35,40–46], examining and demonstrating morphological changes of the brain tissue in some cases [35,42,43,46–48]. The study by Kesari et al. described an increase in ROS formation and an elevation of oxidative stress markers, a marked reduction of antioxidative markers, and increased apoptosis rates in the brain of Wistar rats exposed daily for 2 h to 900 MHz RF-EMF for 45 days (pulsed at 217 Hz; SAR: 0.9 W/kg) [49]. The effects of exposure on this readout were measured once after an exposure period of 45 days, suggesting that prolonged RF-EMF exposure did not lead to exhaustion of ROS production and/or adaptation in this case. Similarly, RF-EMF (915 MHz, 0.79 mW/cm^2) exposure of male Wistar rats for 1 h/day for 1 month resulted in increased oxidative stress and NO formation and reduced antioxidant markers [50]. These purely descriptive studies have limitations, especially when a cell phone was used for exposure, dosimetry was missing, and/or no SAR value or dose was provided. The marker for ROS-related DNA damage, 8-oxo-G, was also increased after RF-EMF exposure (2.45 GHz, whole-body SAR: 0.2 W/kg for 30 days and 1 h/day) in rat brains, while oxidative protein products were not altered [44]. Again, this is a descriptive study, which focused on possible antioxidant effects of garlic extracts, similar to a second study by another group [41], in which RF-EMF (1.8 GHz, whole-body SAR: 0.4 W/kg, 1 h) after 3 weeks of exposure showed an increase in protein oxidation, as well as more NO in the brain. Lipid peroxidation in the brain was found at whole-body SAR values in the range of 0.1–0.3 W/kg [48].

Shahin et al. (2017) also found an increase in ROS and associated changes in the antioxidative defense system in the hypothalamus of female Swiss mice exposed to 1800 MHz RF-EMF for 100 days with no SAR value reported [51]. The same group reported changes in stress-related hormones and associated markers in the hippocampus of male Swiss mice exposed to 2.45 GHz RF-EMF at 0.0146 W/kg SAR for 15, 30, or 60 days [52]. This stress, probably associated with induced NO production and signaling, led to reductions in learning and spatial memory performance of these mice. Long-term exposure for 8 months at 1950 MHz (SAR: 5 W/kg, 2 h/day for 5 days/week) revealed no remarkable differences in programmed cell death, oxidative stress, apoptosis, genotoxicity, and motor activity in 14 month old female mice (C57BL/6J) compared to controls [37]. An increase in oxidative stress was observed in the animals due to age, but RF-EMF exposure did not induce oxidative stress, and the movement behavior of the animals was not affected.

An increase of ROS markers compared to sham-exposed and cage controls was also seen in the spinal cord of very young and middle-aged Sprague-Dawley rats after 900 MHz RF-EMF exposure (1 h/day, calculated whole-body SAR: 0.01 W/kg) for 25 days [53]. Interestingly, biomarkers for antioxidative activity were elevated, indicating that the capacity of the antioxidant system was not yet exhausted and presumably able to counteract ROS formation. Nevertheless, morphological alterations of the spinal cord, such as tissue loss, vacuolation, and changes in myelin integrity, were observed, which might compromise proper neural signal transmission. Such changes, particularly demyelination and scarring of the myelin sheath, occur, for example, in multiple sclerosis. Changes in neurochemical parameters, as well as pathophysiological damage caused by inflammatory processes in various brain regions (i.e., hippocampus and cortex), are usually associated with reduced memory performance, DNA damage, and/or apoptosis. Correlating with the frequency of the radiation, such effects were reported by Megha et al. upon low-intensity RF-EMF exposure (whole-body SAR: about 0.6 mW/kg) [32]. They provided scarce information on the dosimetry, and the actual exposure in the brain is likely to be different from the estimated whole-body SAR values. However, an increased ROS production was found in the brain of rodents at higher SAR values (>1 W/kg) [35,43,54,55]. Ertilav et al. reported an increase in ROS in hippocampal neurons as well as in dorsal root ganglia after RF-EMF exposure of young female Wistar rats [43]. Rats were exposed to 900 or 1800 MHz RF-EMF with 217 Hz pulses for 12 weeks (1 h/day, 5 days/week) at an average whole-body SAR of 0.1 W/kg (local SAR ranging from 0.01–1.1 W/kg with the highest values for the head region). Transient receptor potential cation channel subfamily V member 1 (TRPV1) currents, intracellular calcium concentrations, mitochondrial membrane depolarization, and apoptosis were also significantly enhanced in neuronal cells of exposed animal in a frequency-dependent manner [43]. These observations are potentially relevant due to the role of spinal ganglia the hippocampus in pain transmission and behavior, as well as cognitive functions, although no functional experiments on pain or memory performance have been performed. Neither measurements nor calculations of SAR levels in the brain and spinal cord have been presented and, therefore, the level of exposure of these tissues remains unclear.

An impairment of learning behavior and memory performance by exposure was observed in other studies [56–58]. Tang et al. reported a reduction in memory performance in male Sprague-Dawley rats after 900 MHz RF-EMF exposure (whole-body SAR: 0.016 W/kg, brain SAR: 2 W/kg) for 28 days, associated with changes in the activity of the mitogen-activated protein kinase signaling pathway (mpk-1, external signal-regulated kinase (pERK)) [57]. Similarly, cognitive performance of Fischer-344 rats was decreased after a 900 MHz RF-EMF exposure for 30 days (whole-body SAR: 0.0058 W/kg), which was associated with increased oxidative stress and inflammatory markers in the brain [56]. Exposure to 1500 MHz RF-EMF decreased SOD levels in the brain of Wistar rats, correlating with neural toxicity and changes in learning and memory performance [58]. Thus, the findings of these studies suggest that increased formation of ROS by RF-EMF exposure is associated with an impairment of cognitive abilities.

There have been only a few studies in Wistar rats exposed to a Wireless Fidelity (WiFi) signal (2.45 GHz) [50,59–61]. Othman et al. found impaired neurodevelopment in offspring during the first 17 postnatal days, an increase in cerebral ROS and lipid peroxidation on postnatal day 28 but not 43 after prenatal exposure for 2 h/day, and decreased antioxidant levels (CAT, SOD) [61], indicating an exhaustion of the antioxidative capacity in the brain. In a study from the same group, prenatal WiFi exposure in combination with physical constraint was associated with increased anxiety behavior, motor deficits, and impaired exploratory behavior in adult male rats. Restrained animals, WiFi-exposed rats, and a combination of both resulted in increased oxidative stress in the brain in both sexes [60]. WiFi exposure of adult male Wistar rats alone or with physical constraint impaired the learning behavior and memory performance accompanied by an oxidative stress response in the brain. [59]. Albeit having some methodological shortcomings, the study by Asl et al. also showed increased ROS and NO production in rats exposed to RF-EMF/WiFi (2450 MHz; 0.98 mW/cm^2) [50].

In the context of neurological disorders, the immediate response to short-term RF-EMF exposure was also assessed. In a mouse model with chemically induced epilepsy, the influence of RF-EMF on oxidative stress caused by epilepsy was investigated, exposing them (900 MHz, SAR: 0.3 W/kg) for 15 and 30 min before and/or after induction of the epileptic seizures [62]. While the antioxidant activity was significantly reduced, markers for ROS and lipid peroxidation in the brain were induced, whereby the time-point of RF-EMF exposure was not pivotal for the observed effects. In an Alzheimer's disease model, the stress marker cortisone and markers for oxidative stress in the brain of rats after RF-EMF exposure for 15 min (1.5, 6 W/kg) and for 45 min (6 W/kg) were measured, coincidental with the assessment of memory performance. While oxidative stress in the brain increased, cortisone levels and memory performance of RF-EMF-exposed Alzheimer's animals decreased markedly, an effect that was not observed in wildtype (devoid of Alzheimer) animals [63]. This study indicates that animals with a prior neurodegenerative condition might be more sensitive to RF-EMF exposure.

Compared to neuronal effects of RF-EMF, fewer studies have been published for the low-frequency range in the last decade. A dose-dependent increase in ROS, lipid peroxidation, and decreased antioxidant defense were observed in different brain regions of young male Wistar rats continuously exposed to 50 Hz ELF-MF (50 and 100 µT) for 90 days [64]. More pronounced at the higher field strength, the production of ROS was also increased and the antioxidant response decreased after ELF-MF exposure (100 and 500 µT, 50 Hz) of male Sprague-Dawley rats for 2 h/day for a total duration of 10 months [65]. Similar results were obtained in a study with shorter exposure duration. In male rats exposed to ELF-MF (500 µT, 50 Hz) for 7 days, ROS was increased in various areas of the brain and increased lipid peroxidation and activity of the protective antioxidative mechanisms were observed [66].

At higher magnetic field strengths (2.3 mT), increased ROS production was observed in the cerebellum of male mice (Balb/C) after a short exposure (3 h) with 60 Hz ELF-MF, while some antioxidative markers were elevated (SOD, ascorbic acid) and others remained unchanged (GSH, GPx) [67]. Apparently, antioxidative processes are initiated after such a short exposure period. However, it is not expected that the antioxidative system is already exhausted or impaired, indicating a state of oxidative stress as in studies with longer exposure. For example, ROS production, as well as lipid peroxidation, in the brain of young male Sprague-Dawley rats was altered after 40 Hz ELF-MF exposure (7 mT), depending on the duration of daily exposure (30 versus 60 min) for 10 days [68]. In this situation, 30 min of daily exposure was sufficient to increase lipid peroxidation, while detectable ROS formation required 60 min exposure, suggesting a threshold for exposure duration or cumulative dose.

As mentioned before, confinement stress caused by animal exposure in tubes can lead to systemic oxidative stress. In the study by Martinez-Samarano et al., an alteration of various biomarkers for oxidative stress (SOD, CAT, NO) and increased ROS levels were measured in the brain of male rats after acute 60 Hz ELF-MF exposure for 2 h (2.4 mT), whether in cages or in tubes [69]. SOD levels were significantly lower in restrained ELF-MF-exposed animals compared to animals in cage controls and the respective sham controls. CAT levels were reduced in ELF-MF-exposed animals in cages when compared to the sham control, but a difference in CAT levels was found when the rats exposed in tubes were compared to the corresponding sham control. NO levels were significantly lower in rats exposed to ELF-MF in tubes compared to all other groups. These data show that ELF-MF induces an adaptive response even at short-term exposure, leading to activation of protective antioxidative measures. The stress hormone cortisone was elevated only in control animals that spent time in tubes, while ELF-MF exposure did not alter the outcome [69]. There are also indications of inflammatory response in the brain. NO was elevated in various brain regions of male Sprague-Dawley rats exposed to a 60 Hz ELF-MF (2 mT) for 5 days, which was supported by an increased level of nNOS [70]. Nevertheless, the number of neurons remained unchanged and ultrastructural examinations of the mitochondria did not reveal any differences compared to the controls. As NO can react with superoxide, this could then lead to damage of DNA and proteins, depending on its extent. However, no further investigations in this direction were performed, precluding a firm statement about damage to both biomolecules by ELF-MF.

In addition to duration and dose of exposure, the age of the animals is also a factor influencing the defense mechanisms against stress factors since defense and counter-regulatory mechanisms decrease with age [71]. In line with that notion, Falone et al. showed that the extent of antioxidative defense mechanisms in the cerebral cortex of female Sprague-Dawley rats depended on age, regardless of exposure [72]. The antioxidative capacity was less efficient in 19 month old animals compared to 3 month old animals, yet an influence of 50 Hz ELF-MF exposure (100 μT) for 10 days on the antioxidative activity was observed overall. CAT activity was significantly decreased and SOD and GSH reductase were increased in the young rats after ELF-MF exposure. In young animals, this was accompanied by signs of increased neuromodulation (elevated levels of nerve growth factor NGF and tropomyosin receptor kinase A TrKA). Such neurotrophins cause targeted connections between neurons and lead to activation of cellular signaling pathways, which may ultimately result in an antiapoptotic effect. In contrast, older rats were not able to stimulate such protective processes, and a marked reduction in antioxidative parameters was found in the brain [72,73]. These results suggest that EMF might be a risk factor in older individuals due to their reduced capacity of antioxidative defense.

Environmental cofactors may also modulate the occurrence and response of oxidative stress. In the brain of Kumming mice, the effect of aluminum with and without 50 Hz ELF-MF irradiation (2 mT) for 6 days/week and 8 weeks on the occurrence of oxidative stress, as well as Tau and phosphorylated Tau proteins, was investigated. The Tau protein is important in neurodegenerative syndromes such as Alzheimer's disease, as it binds to microtubules in cells, regulating their cohesion. ELF-MF exposure caused an increase in ROS and a reduction in the measured antioxidative biomarkers, while the additional administration of aluminum did not promote any further impairment [74]. Structural abnormalities, a reduction in the number of neurons, and changes in the phosphorylated form of Tau at S404 and S396 indicated neurodegenerative effects of subchronic ELF-MF exposure, which was supported by the impairment of learning and memory performance in ELF-MF-exposed animals.

Overall, the studies related to RF-EMF and ELF-MF show that various factors are influencing the response to EMF exposure. In addition to duration and dose of exposure, adaptive processes and age-related capacities to respond to oxidative stress are of central importance.

3.2. Observations in EMF-Exposed Cultured Neuronal Cells

In support of the findings in animals, EMF-induced oxidative stress was also most frequently investigated in cultured cells of neuronal origin (Supplementary Materials, Tables S2 and S4). In the last 10 years, more than 30 manuscripts have been published, in which, among other endpoints, the influence of EMF on the formation of radicals and ROS or biomarkers for oxidative stress was analyzed, about half in the low- and half in the radio-frequency range. The cell models used were largely tumor cells of neuronal origin (neuroblastoma: SH-SY5Y, NB69, Neuro-2a; glioma: U-87MG, C6; pheochromocytoma: PC12), in addition to established cell lines (HT22) and primary neurons of the brain, as well as astrocytes from humans and rodents.

The influence of ELF-MF was mainly investigated in tumor cell lines, where exposure was frequently found to influence ROS formation or markers of oxidative stress and to lead to changes in the antioxidative defense system. It is important to note that tumor cells often have an intrinsically disturbed oxidative balance and may, therefore, react differently to EMF or other treatments than a normal cell. However, primary neurons from the brain also reacted to repeated 50 Hz ELF-MF exposure at a flux density of 2 mT by an increased production of ROS, an upregulation of the NADPH oxidase NOX2, and faster neuronal cell death, especially pronounced in older cell cultures [75]. This indicates that the findings from the experiments with tumor cells are at least partially transferable to normal and immortalized cells. For example, slightly elevated values for superoxide and H_2O_2 were found in SH-SY5Y neuroblastoma cells [76–78] when exposed to a 1 mT field for 1–3 days. In addition, the increase in ROS was attenuated by SOD administration [79] and changes in various markers of oxidative stress (CAT activity, oxidative protein modification) were observed. On the other hand, the increase in ROS appeared to be more pronounced when acute cell responses, about 1 to 6 h after exposure start, were evaluated [78,80]. Simultaneously, an increased activity of the NO synthase was observed, which might indicate a function of ROS and NO as a signaling molecule in this context. In fact, there is evidence for ROS-mediated alteration of cellular signaling pathways by ELF-MF exposure from studies with neuroblastoma cells [77,81]. In addition, it was found in PC-12 tumor cells that a short ELF-MF exposure of 30 min (0.1 and 1 mT) induced a differentiation process mediated by a rapid increase in ROS formation [82]. This increase in ROS did not occur when the cells were advanced in the differentiation process or exposed for a longer period of time [82,83]. Similar mechanisms involving ROS formation as a signaling molecule seemed to work when mesenchymal stem cells from human bone marrow were differentiated into neural cells under 50 Hz ELF-MF exposure (1 mT) [84,85]. Here, the efficiency and proportion of differentiation to the distinct neural cell types was altered by exposure, most likely because the increased ROS formation triggered or modified signaling cascades.

It is possible that a constant stimulation of ROS formation cumulatively boosts the antioxidative defense systems. Therefore, after short exposures, little or no evidence of antioxidative stress markers, such as the ratio of GSH/GSSG, can be detected [86], while, after longer exposure, increases in these markers, as well as changes in cell response to additional stress, were observed [76,87]. In this context, it is also worth mentioning that similar observations were also made for weaker ELF-MF ($\leq$100 µT) in combination with other triggers of oxidative stress, whereby the cellular adaptations and consequences were still detectable for a prolonged time [88–91]. Hence, there is quite consistent evidence that exposure to 50 Hz ELF-MF leads to increased formation of ROS in cultured cells of neuronal origin. As a consequence, activation of a variety of cellular regulatory mechanisms triggers corresponding cell responses, whereas it may also lead to persistent oxidative stress situations.

Similar observations were made in RF-EMF-exposed neuronal cells, although the findings were less consistent and partly even contradictory. This could also be due to the technically and dosimetrically more demanding implementation in this frequency range and the diversity of the investigated RF-EMFs with respect to dose, carrier frequencies, inclusion of signal modulation, etc. For example, in isolated rat neurons exposed to a 1.8 GHz global system for mobile communications/second generation (GSM) signal for 24 h, increased ROS formation, in addition to signs of DNA damage and reduced functionality of mitochondria, was found at 2 W/kg SAR [92], whereas this increase was only significantly detectable at 4 W/kg SAR in another study [93]. In isolated astrocytes of humans, mice and rats, however, there was no evidence of an increase in ROS by 900 MHz GSM signals for 24 h, and there was even less ROS produced in the mitochondria (SAR: 0.2 W/kg) [94]. Similarly, no signs of inflammation, such as more iNOS or NO formation, were found in astrocytes after exposure to 1.8 GHz RF-EMF for 1–24 h (SAR: 1 W/kg) [95], although an acute increase in ROS after 20 min of exposure to modulated but not unmodulated 900 MHz RF-EMF was found [96]. On the other hand, in a mouse neuronal cell line, exposure to a 1.95 GHz RF-EMF (UMTS/3G signal) showed marginal effects on ROS formation and other parameters on its own, but differentially modulated signaling pathways and cytotoxicity when ROS formation was triggered by glutamate or β-amyloid [97,98].

A series of studies have been conducted with neuronal tumor cells. No increase in ROS formation was found in SH-SY5Y neuroblastoma or U-87MG glioma cells after acute exposure to 872 MHz RF-EMF (GSM signal or carrier wave, SAR: 5 W/kg) [99,100], a 900 MHz GSM signal (SAR: 4 W/kg, 2 min on/off) [101], a combination of modulated 867/1950 MHz RF-EMFs (SAR: 4 W/kg) [102], and a 1.8 GHz GSM signal (SAR: 2/10 W/kg) [103]. In short-term co-exposure experiments, the effect of an ROS-triggering substance such as menadione and H_2O_2 was amplified by these RF-EMFs [99,102]. In contrast, these cell types reacted to a non-modulated 1.8 GHz RF-EMF and comparable exposure duration with the formation of ROS, oxidative protein modification, lipid peroxidation, and alteration of the antioxidative defense system (GSH) [104,105]. Similar to the observations for ELF-MF, the ROS increase seems to be more prominent after short rather than after continuous ($\geq$12 h) RF-EMF exposure [94,103,105]. For prolonged exposure, there are once more indications for a boost of the antioxidative defense system, an impact on mitochondrial function and autophagy activity [101,106], and even an accumulation of DNA damage and cell death [92,105,107].

3.3. *Assessment of EMF-Induced Oxidative Stress in the Nervous System*

In general, a distinction must be made between studies that are purely descriptive and those that simultaneously investigate functional effects, such as learning and memory performance. The latter ones provide more information on a possible health-relevant impact on the animals due to increased oxidative stress caused by EMF exposure. It is also important to note that, for the assessment of health relevance, ROS formation and temporary oxidative stress are not harmful per se [1,3,4,23]. These reactive molecules are also part of physiological processes and fulfil functions, for example, in the immune response or the correct formation of protein structures. Damage with possible health relevance only occurs if the redox equilibrium, which is controlled and maintained by sensors, cellular signaling pathways, and protective antioxidative mechanisms, is disturbed over a long period of time, either permanently or repeatedly. If the latter is the case, various physiological processes such as cell proliferation, neuronal differentiation and activity, and development are affected. ROS formation and decreased antioxidative counter-regulation also occur in aging processes. Therefore, models investigating the influence of EMF exposure on the redox system are of interest and importance for a possible impairment of old individuals or those with pre-existing damage (neurodegeneration). Oxidative stress is the cause and/or consequence of neurodegenerative syndromes such as Alzheimer's and Parkinson's disease, which are accompanied by reduced learning and memory performance.

An increased occurrence of ROS, as well as the burdening and exhaustion of antioxidative mechanisms after exposure to different EMF in the radiofrequency range and SAR, even at values below the recommended regulatory limits, and damage to the DNA were associated with prolonged exposure over weeks or months, applied in many cases only for a few hours per day [29–34]. However, one study also reported that recovery and a return to normal values after the end of exposure occurred [35].

Studies on mechanisms such as those related to calcium channels are particularly informative as calcium concentration-dependent cellular responses may result in a multitude of pleiotropic effects [9]. Voltage-gated calcium channels were shown to be activated by nonthermal pulse-modulated 27 MHz RF-EMF, leading to an increase in NO [108] while nonselective calcium channels such as transient receptor potential (TRP) channels are activated by oxidative stress [109,110]. For instance, the TRPV1 channel, belonging to the calcium-permeable TRP superfamily, can be activated not only by stimuli such as heat and capsaicin, but also by oxidative stress. Activation of TRPV channels by oxidative stress/EMF was demonstrated to result in an increase in neuronal calcium concentrations that may lead to physiological changes and pathological processes such as apoptosis [43,111,112]. The occurrence of TRPV1 is particularly high in neurons of the hippocampus and in spinal ganglia, where it is probably involved in the transmission of pain, which is impaired in neurodegenerative processes [109,110].

In part, the changes in redox balance were accompanied by morphological changes that resemble those in neurodegenerative diseases [34,35,42,43,46–48,53]. In general, studies, in which ROS, antioxidative markers, learning behavior, and memory performance were examined, suggest an impairment of neuronal functions of the animals. Thus, there is evidence that, at least in animal models, increased ROS production by EMF is associated with an impairment of cognitive abilities [51,52,56–60]. Notably, RF-EMF exposure affected the memory performance of animals with neurodegenerative pre-damage of the brain (i.e., Alzheimer's disease model) more than in control wildtype animals [63], indicating an enhancement of conditions of impaired learning behavior by RF-EMF. In addition to such pre-existing conditions, other environmental or risk factors may also play a role in whether and to what extent oxidative stress due to EMF exposure occurs. There is evidence that age is such a risk factor [72]. Due to their reduced antioxidative capacity in the brain, older individuals are less efficient in compensating for increased ROS formation, and adaptive processes are exhausted more quickly than in young individuals [71]. Newborns are also more vulnerable to oxidative stress, as antioxidative protection mechanisms are not fully developed in the first days or weeks of life, depending on the species.

Methodological factors must also be taken into consideration when evaluating experimental studies. Often, RF-EMF exposure was performed in carousel exposure systems, in which the animals are placed into narrow tubes during exposure, facilitating a homogeneous and defined exposure. However, this procedure provides a source of error if the animals are not trained in advance, since restraint stress can also lead to oxidative stress [69]. In these experiments, sham controls and prior training of the animals to the conditions of exposure are important. In addition to increased ROS production, a change in the anxiety behavior, but not in memory performance, was found after WiFi exposure of rats exposed in tubes, which was enhanced by the exposure [59,60].

ROS formation and impairment of antioxidative protection measures by EMF were demonstrated in cell studies with neurons or neural cells, which aim at understanding the mechanisms underlying the observations in animal models. There is consistent evidence that cellular signaling pathways regulated by ROS are affected [77,81,82,97,98]. The extent of induction, as well as the possibility of counter-regulation has to be considered, presumably requiring a threshold level or persistence to translate to health impairment. It seems that the degree of cell differentiation or age is critical; cells that were further differentiated generally were less sensitive compared to undifferentiated cells or cells in an early stage of differentiation [75,82,84,85]. It is noteworthy that the induction of ROS and signs of oxidative stress appear to be more reproducible in neural cells exposed to ELF-MF than to RF-EMF [75–82,92–94,96–105,113]. Higher doses of RF-EMF exposure mostly resulted in more pronounced effects, although not consistently, and a temperature increase or other confounders cannot always be excluded [92,93,96,99–103]. Other methodological factors, such as keeping sham controls in a separate incubator, pose a risk of false-positive findings [114,115]. For example, vibrations, as well as EMF of the incubator or its inadequate shielding, come into play, and it cannot be excluded that these factors influenced the measurement parameters recorded in some studies. The duration of exposure seems to play a role, whereas a shorter exposure for few hours rather than prolonged ones led to increased ROS production and a temporal reduction in antioxidative processes [78,80,94,96,103,105].

4. EMF Effects on the Blood and Immune System

The influence of technology-related EMF on cells of the immune system has also been a frequent topic of investigation in recent years [8,11,12]. The functioning of the immune system is inseparably connected to the formation of ROS and NO. ROS and NO play a vital role in the elimination of foreign or damaged cells by phagocytosis and are involved in the inflammatory reaction and activation of the immune response [2,21]. In this respect, it is conceivable that suppression, as well as a constant activation, of these processes by EMF could lead to impairment of health. Therefore, the influence of EMF on various aspects of immune responses and the development of hematopoietic cells and the microglia cells as a functional equivalent in the central nervous system have been studied (Supplementary Materials, Tables S1–S4).

While several publications on oxidative stress and EMF exposure in isolated and cultured blood and immune cells are available, the number of animal studies is limited, whereof only some of them provided information on ROS markers in blood.

4.1. Oxidative Stress in EMF-Exposed Animals

Exogenous influences, such as stress, can alter the organism's response to subsequent stimuli. In a short-term study, mice were exposed to 900 MHz RF-EMF (SAR: 0.5 W/kg) 4 h/day for 1 week before treating them with the cancer medication bleomycin [38]. This substance acts by oxidation of molecules, leading to oxidative stress, and causes DNA damage among other implications. Interestingly, leukocytes of RF-EMF-exposed animals were less damaged by bleomycin compared to controls, and ROS was decreased in the plasma and some tissues, while SOD was increased in the lung [38]. These findings suggest that RF-EMF exposure may cause systemic changes, which in turn affects the cellular response to other stressors. This phenomenon is known as "adaptive response", which is likely to play an important role in real life situations where many stress and environmental stimuli occur simultaneously. Related findings were obtained in young and adolescent Wistar rats after 900 MHz RF-EMF exposure (SAR: 0.28–0.78 W/kg) [116]. ROS and oxidative stress markers were measured directly after 45 days of exposure for 2 h per day or following a recovery period of 15 days [116]. This approach facilitates the determination of postexposure persistence and the ability of the organism to counteract the oxidative stress. RF-EMF increased the antioxidative activity in all lymphoid organs regardless of the age, and that the recovery period was insufficient to return to normal SOD levels when exposure was started at 2 weeks compared to the animals at 10 weeks of age. As oxidative stress biomarkers were elevated in all animals after RF-EMF exposure, this difference may originate from the fact that the enzymes of the protective antioxidative defense system are not yet fully developed or present in the very young rats. Depending on the marker, the normalization in the recovery phase was more successful in the 10 week old rats. In most of the lymphoid organs, as well as in plasma and lymphocytes, increased lipid peroxidation was seen directly after exposure and at the end of the recovery phase [116]. This comprehensive and well-documented study shows, on the one hand, that the oxidative stress situation may persist for a longer period of time and, on the other hand, that very young individuals are less able to compensate for the increase in ROS.

In Wistar rats, similar results were demonstrated, including increased lipid peroxidation due to exposure to 2.45 GHz WiFi-like signals for 35 days (50 Hz pulses, whole-body SAR: 0.14 W/kg) in the spleen [48] and for 28 days (217 Hz pulses, SAR: 0.143 W/kg, 45 min/day) in plasma and erythrocytes [117], accompanied by a reduced activity of antioxidative markers. Furthermore, oxidative DNA (8-oxo-G) and protein products, indicating oxidative stress, were elevated in plasma cells of rats after a daily 1 h exposure to 2.45 GHz RF-EMF (whole-body SAR: 0.2 W/kg) for 30 days [44]. Signs of oxidative stress were described in RF-EMF-exposed mice. Changes in ROS and enzymes of antioxidative defense (SOD, CAT, glutathione *S*-transferase (GST)) were found in blood, as well as in the liver, kidneys, and ovaries, of pregnant Parkes mice exposed to 2450 MHz RF-EMF (SAR: 0.023 W/kg) for 45 days [118]. The same group also reported changes in stress-related hormones and associated markers in the blood of Swiss mice exposed to 2450 MHz RF-EMF (SAR: 0.0146 W/kg) for 15, 30, or 60 days [52]. In contrast, no effects on oxidative stress, lipid peroxidation, or elevated NO levels were measured in the blood serum of Wistar rats upon exposure to 1.8 GHz RF-EMF (whole-body SAR: 0.4 W/kg) daily for 1 h for 3 weeks [41]. Likewise, lipid peroxidation and reduced GSH were not increased in the blood of rats that were exposed to UMTS-modulated RF-EMF daily for 40 min for 2 weeks [119]. However, the animals were exposed using a cell phone in talk mode in their cages, which is associated with large fluctuations and uncertainty regarding exposure dose.

Recent animal studies on oxidative stress induced by exposure to 50 Hz ELF-MF are scarce. Exposure for 10 months at a field strength of 100 μT to male Sprague-Dawley rats resulted in modifications of DNA bases (8-oxo-G and others) in white blood cells, which are produced by oxidative processes and may be mutagenic [120]. Interestingly, these effects were no longer observed at a higher field strength of 500 μT. However, no direct conclusions can be drawn, since DNA damage was not investigated. Increased ROS production and lipid peroxidation were measured in the plasma of female rats after ELF-MF (50 Hz, 100 μT) exposure for 3 h/day. These effects seemed to be cumulative with duration of exposure, being stronger for 100 days than for 50 days of exposure [121].

4.2. Radical Formation in EMF-Exposed Cells of the Blood and Immune System

Cancer cell lines were used as a model system in the majority of in vitro studies, e.g., various myeloid leukemic cells such as THP-1 monocytes, K562 myelocytes, NB-4 and HL-60 promyelocytes, and RAW 264.7 macrophages. In addition, established microglia cells (human: HMO6, CHME-5; mouse: N9) and isolated hematopoietic stem cells, monocytes, macrophages, and T cells from humans and mice were employed (Supplementary Materials, Tables S2 and S4).

An increase in superoxide formation was observed in K562 leukemic cells after 50 Hz ELF-MF exposure for 1 h with relatively low flux densities (25, 50, 100 μT) [122]. In this cell system, the time of analysis also seems to play a role. A transient stimulation of CAT activity and a time window for increased production of superoxide and iNOS were found for ELF-MF exposure (1 mT) [123]. In this case, the superoxide was generated by cytochrome P450 enzymes, which are phase I enzymes that play an important role in biotransformation of substances, including food components and pharmaceuticals. Exposure also altered the cell response to the tumor promoter phorbol-12-myristate-13-acetate (PMA) that triggers cell differentiation processes involving ROS. Prolonged or repeated ELF-MF exposure, however, provided little evidence for oxidative stress and ROS formation, although here an influence of exposure on cell responses to other factors was also found [124,125]. Accompanied by stimulation of ROS formation, on the other hand, prolonged 50 Hz ELF-MF exposure (2 mT) enhanced the differentiation of NB-4 promyelocytic leukemia cells by all-*trans*-retinoic acid (ATRA) but not PMA [126].

There have also been some studies, which looked at effects of ELF-MF on phagocytosis and immune function. For example, it was found in the THP-1 human monocyte leukemia cell line that ELF-MF exposure (1 mT) led to increased iNOS activity and NO production, whereas the activity of the antioxidative enzymes SOD and CAT were reduced [127,128]. In both cases, additional exposure led to changes in the immune response triggered by staphylococci or lipopolysaccharides (LPS). In this regard, 50 Hz ELF-MF exposure modulated the cellular response to the LPS treatment and underlying signaling cascades, involving the antioxidative heme oxigenase-1 (HO-1) that counteracts the induced ROS formation and changes in oxidative status [129]. An enhancing effect of 60 Hz ELF-MF (0.8 mT) on the induced immune response and NO production was found in RAW246.7 mouse macrophage tumor cells [130], whereas a reduction in NO production by LPS was reported in the same cell line exposed to 50 Hz ELF-MF (0.5 mT) [131]. These contrasting effects may be due to the different sequence of treatments. In isolated mouse macrophages, a slightly increased ROS production was observed, resembling to some extent an induced immune response, but the signaling pathways superimposed only partially [132]. This could indicate that ELF-MF does not trigger a genuine immune response, nevertheless creating a cellular situation that leads to a change in the response to further stimuli or stress situations. For example, previous exposures to 10 and 50 Hz, but not to 100 Hz, ELF-MF (1 mT) had a protective effect, reducing apoptosis and ROS formation in human microglia cells when they were metabolically stressed by deprivation of oxygen and sugar, i.e., conditions similar to those that occur in brain ischemia [133].

Evidence for an inflammatory cell response regarding iNOS activity and NO production was found in mouse microglia cells exposed to a GSM signal (SAR: 2 W/kg) [95] for 24 h or for a short time (20 min) to pulsed 2.45 GHz RF-EMF [134,135]. In both situations, activation of STAT3 (signal transducer and activator of transcription 3) and mitogen-activated protein kinase (MAPK) signaling pathways was observed, as well as changes in the production of cellular messengers and a reduction in microglial phagocytosis. It should be noted that exposure to pulsed 2.45 GHz RF-EMF with 6 W/kg SAR is a situation or signal type that would hardly occur as an environmental factor [134,135]. On the other hand, exposure of this cell type to a 900 MHz GSM signal (SAR: 4 W/kg) temporarily altered the activity of the mitochondrial cytochrome c oxidase without leading to oxidative stress [101]. A decrease in phagocytosis was also observed in RAW264.7 macrophages cells, accompanied by an RF-EMF-induced increase in NO synthesis [136]. This effect increased with the duration of exposure, regardless of whether 900 MHz, 2.45 GHz, or a combination (SAR: 80–400 mW) was applied. On the other hand, 2.45 GHz RF-EMF (SAR: 0.4 W/kg) promoted phagocytosis of co-exposed black carbon particles, changed the immune response, and increased NO production and cell toxicity [137].

In this regard, it is worth mentioning that an increase in oxidative stress by RF-EMF was observed in populations of immune cells from human blood enriched by flow cytometry [138–140]. However, it should be noted that, in contrast to cultured cells/cell lines, this does not necessarily reflect an immune reaction, but possibly an enhancement of the cell aging or cell death process because of a strong stress situation due to the removal from their normal environment. Furthermore, leukemic HL60 cells and differentiating $CD34^+$ (surface marker "cluster of differentiation 34") human blood stem cells (HSCs) were also investigated for effects of RF-EMF exposure on the oxidative balance. In both cell types, no evidence was found that exposure to 900 MHz GSM, 1.95 GHz UMTS, and 2.53 GHz LTE signals at SAR values of 0.5–4 W/kg led to increased ROS formation after either short (4 h) or prolonged exposure [141]. In another study with stem and other blood cells, a temporary increase in ROS formation was observed after 1 h of UMTS exposure

(SAR: 40 mW/kg) [142]. This was also the case in leukemic HL60 cells, in which 900 MHz RF-EMF at a calculated SAR value of 0.25 mW/kg triggered an increase in ROS formation, which was prominently detectable after 30 min, attenuated after 4 h, and vanished after 24 h of exposure [143]. ROS levels correlated well with a temporary increase in oxidative DNA damage, as well as the energy production of the mitochondria. In the same cell line, signs of increased lipid peroxidation (MDA) were also observed when the cells were exposed to 2.45 GHz RF-EMF with 217 Hz pulses at estimated 0.1 W/kg SAR, whereas no change in GSH and GPx activity was evident [144].

4.3. Assessment of EMF Effects on Blood and Immune Organs

ROS play an important role in the elimination of foreign or damaged cells, while they are also involved in inflammatory reactions and the activation of the immune response [21]. Long-term inhibition and repeated activation of ROS are likely to cause health effects.

There is evidence that EMF affects the response to other (stress) factors [38,124–126,129,130,137]. Such a crosstalk between cell responses is important in real life, since humans and animals are exposed to different and changing stress and environmental factors, in contrast to experimental studies. For example, chemically induced oxidative stress reduced the production of ROS in animals after subsequent exposure to RF-EMF, indicating an adaptive response [38]. Observations in this direction have also been made in cell studies. For instance, it was shown that immune responses and phagocytosis were altered by RF-EMF exposure [95,134–137].

Similar to the findings reported for the central nervous system, there are indications that effects of EMF exposure are age-dependent in the lymphoid system. Very young animals could not compensate for oxidative stress, even after a recovery period, whereas this was possible in older animals after complete development of the antioxidative protective system [116]. Moreover, in cultured cells, the time of analysis of oxidative stress seems to play a role, and short-term exposure led to an increase of oxidative stress in lymphoid and leukemic cells [123,143]. This increase was mostly temporary, and the triggered processes were partly similar to a genuine immune response [132].

Overall, however, only a few animal and cell studies on the influence of EMF exposure on oxidative stress and defense of the immune system are available. At present, the data available do not allow a conclusive assessment of possible health effects. Nevertheless, dependencies on preconditions, age, and exposure duration are likely similar to the nervous system.

5. EMF Exposure and Oxidative Stress: Effects on Reproduction

5.1. In Animals

Influences of EMF on male reproductive organs and sperm, as well as their precursors, were investigated in more than 30 animal studies (Supplementary Materials, Tables S1 and S3). In Sprague Dawley rats exposed to 900 MHz RF-EMF (whole-body SAR: 0.0067 W/kg) for 1 h/day for 21 days, testicular weight decreased and various morphological changes were observed, including mitochondrial integrity, apoptosis, and increased antioxidative activity [145]. In adult Wistar rats, significant changes in sperm count and vitality, morphological changes, and increased ROS levels and lipid peroxidation in sperm and their precursor stages were found after RF-EMF exposure with a 3G/UMTS signal (SAR: 0.26 W/kg) for 45 days (2 h/day), concomitantly with a decrease in sperm with active mitochondria [146]. Similar results were reported by Shahin et al. [55]. Yet again, significant decreases in sperm count and vitality were found, which were associated with an increase in various oxidative stress markers (ROS, NO, MDA) and a decrease in antioxidative activities (SOD, GST, CAT). In addition, the amount of iNOS was increased in the precursors of sperm and in Leydig cells [55]. These findings indicate functional and morphological impairment of spermatozoa by RF-EMF exposure, associated with an increase in ROS. Liu et al. reported ROS formation and oxidative stress in rat sperm, as well as tissue changes and increased apoptosis, after exposure to 900 MHz RF-EMF (SAR:

0.66 W/kg) for 2 h/day and 50 days [147]. An increase in ROS, resulting in histological and morphological changes of testes and germ cells, as well as DNA damage, was found in Swiss mice after exposure to 900 MHz RF-EMF (SAR: 0.0054–0.0516 W/kg) twice for 3 h/day for 35 days [148].

Increased lipid peroxidation after 2.45 GHz RF-EMF exposure (50 Hz pulses, whole-body SAR: 0.14 W/kg, 2 h/day) for 3 weeks was found in testes of rats [48]. Exposure to 2.45 GHz RF-EMF (217 Hz-pulsed, whole-body SAR: 0.143 W/kg) of male Wistar rats for 30 days at 1 h/day did not change GSH levels and increased lipid peroxidation in testicular tissue, which could be counteracted by melatonin treatment [149]. Analogous findings were reported for male Wistar rats exposed to 900 MHz (pulsed, whole-body SAR: 1.2 W/kg) for 2 h/day for a total of 3 weeks. Lipid peroxidation and NO production were enhanced and GSH levels were decreased [150]. Pandey et al. reported mitochondrial damage, cellular damage, and DNA damage in spermatocytes of male Swiss mice exposed for 35 days to 900 MHz RF-EMF (SAR: 0.0045–0.0056 W/kg, attributing them to oxidative stress [151]. Exposure to a 900 MHz RF-EMF (SAR: 1.075 W/kg) for 2 h/day for 8 weeks resulted in changes in levels of MDA and the ROS scavenger GST in male Wistar rats [152]. The same authors also reported a significant increase in ROS, alterations of oxidative stress markers, DNA damage, increased apoptosis, inflammation, and tissue toxicity in testes of Swiss mice exposed to 1.8 GHz RF-EMF (SAR: 0.05 W/kg) for 120 days [153]. RF-EMF exposure of male Wistar rats at 900 MHz, 2 h/day for 35 days (SAR: 0.9 W/kg) [154], as well as 4 h/day for 20, 40, and 60 days (SAR: 0.043–0.135) [155], revealed alterations in various oxidative stress markers in the testes, with one study also demonstrating DNA damage [154]. Similar findings were obtained in male Wistar rats after exposure to a 900/1800 MHz dual-band mobile phone (no fields measured or SAR calculated) for 1, 2, or 3 h/day [156]. In one study, combined 900/1800/1900 MHz RF-EMF exposure for 15, 30, and 60 min/day for 14 days (SAR: 0.9 W/kg) resulted in changes in oxidative stress markers and tissue toxicity in testes of Wistar rats [157].

Previous insults or existing diseases, such as diabetes, can make the organism more sensitive to exogenous stressors [158]. Increased lipid peroxidation, NO production, and a decrease in GSH were found in the testicular tissue of male Wistar rats after exposure to 50 Hz ELF-MF (8.2 mT) and 2.1 GHz RF-EMF (SAR: 0.23 W/kg) for 20 min/day for 4 weeks. These effects were more pronounced in rats with diabetes than in healthy animals [158].

RF-EMF effects on female reproduction were also performed. For instance, RF-EMF exposure for 1 h/day, 5 days/week for 52 weeks at all investigated frequencies (900, 1800, 2450 MHz, SAR: 0.1 W/kg) resulted in an increase in lipid peroxidation but no significant changes in other oxidative stress markers in the uteri of female Wistar rats [112]. In the endometrium of Wistar rats, increased lipid peroxidation (MDA), NO production, and decreased measured antioxidative biomarkers (GSH, GPx, CAT) were found after exposure to a 217 Hz-pulsed 900 MHz RF-EMF, with a whole-body SAR of 0.014–4 W/kg for 30 min/day for 30 days [159]. However, the large SAR fluctuations with potential temperature increases entail some uncertainty whether the observed morphological changes, apoptosis, and immune modulation occurred due to the oxidative stress and/or by tissue warming. Similarly, increased ROS production and associated changes in oxidative stress markers were found in the uterus and the ovaries of female Swiss mice exposed to 1.8 GHz RF-EMF for 100 days. However, no SAR values were reported [51]. Another study in female mice demonstrated increased oxidative stress and morphological alterations of the implantation sites of the embryos in the placenta when female Parkes mice were exposed to 2.45 GHz RF-EMF (SAR: 0.023 W/kg) for 2 h/day for 45 days [118]. This resulted in impaired reproduction, measured as implantation failure or resorption of the embryos, which might have been caused by increased formation of ROS. This affects a very early stage of pregnancy (corresponding to days 7–8 in humans) when the blastocyst attaches to the uterine wall.

Regarding development, it is also of relevance whether exposure of dams causes oxidative stress in the fetuses and whether this results in any kind of impairments in the offspring. In the study by Özorak et al., Wistar rats were exposed to 217 Hz-pulsed 900 MHz, 1800 MHz, or 2.45 GHz RF-EMF (whole-body SAR: 0.18 W/kg; 10 V/m) for 60 min/day in the uterus and up to 6 weeks after birth [160]. For all three frequencies, lipid peroxidation in the newborns was initially decreased (week 4 after birth), while it was significantly higher at 6 weeks. Antioxidative markers in RF-EMF-exposed rats were significantly lower than those of the control animals at all three time-points measured (4, 5, and 6 weeks postpartum) and at all frequencies [160]. ROS were not analyzed, but the increased lipid peroxidation in RF-EMF exposed animals at 6 weeks of life and the decrease in antioxidative markers suggest an oxidative stress situation. Increased ROS production was also found in ovaries of female Wistar rats after 2.45 GHz RF-EMF exposure (SAR: 0.1 W/kg) for 1 h/day in utero and/or 1 h/day from postnatal day 21 to puberty [161].

5.2. In Cultured Cells

The functionality of cells of the reproductive system was also examined for effects of EMF (Supplementary Materials, Tables S2 and S4). Due to their temperature sensitivity, developmental characteristics, and availability, mainly male germ cells and cells from the reproductive organ were employed. Among them, two mouse cell lines, GC-1 and GC-2, representing two stages of sperm development, were used most frequently, but sperm and spermatogonia from humans and mice, as well as the testosterone-producing Leydig cells from testicular tissue, were also assessed.

The majority of studies published in the last 10 years focused on investigations of RF-EMF effects, such that hardly any recent data are available on the influence of 50 Hz ELF-MF on oxidative balance. In spermatogenic GC-1 but not in GC-2 mouse cell lines, a consistent increase in superoxide was found after exposure to 50 Hz ELF-MF (2.5 mT) for 2 h, while NO levels remained unchanged [162,163]. Here, however, changes after a recovery period of 2 days and nonimmediate responses were measured; thus, these effects are rather indications of long-term or secondary effects. The influence of prolonged ELF-MF exposure for 24 h (1, 2, 3 mT) on the genome was investigated in another study with GC-2 cells, with a marginal increase in DNA damage at the highest dose, which was interpreted as a consequence of oxidative stress [164], but data about ROS formation or oxidative stress were not provided.

Ex vivo investigation yielded ambivalent observations and conclusions in a few studies with human sperm on the influence of RF-EMF with respect to oxidative stress and quality, although similar exposure durations (45–90 min) and doses (SAR: 1–6 W/kg) were applied [165–168]. Two studies reported no signs of increased ROS, no oxidative DNA damage, or any other negative effects such as induced cell death and reduction in sperm quality, when sperm was exposed to a 900 MHz GSM or a 1.95 GHz UMTS signal [166,167]. In contrast, oxidative stress and, in some cases, massive DNA damage and loss of sperm vitality were observed after exposure to 900 MHz GSM or 2.45 GHz WiFi signal [165,168]. However, it has to be noted that the two studies without significant effects were conducted under controlled temperature and exposure conditions, while user devices were applied in the other two. It needs to be considered that exposure of cells with commercial user devices (e.g., cell phones) often entail many uncertainties, confounders, and/or fluctuations in exposure.

After 24 h of exposure with a 1.8 GHz RF-EMF (GSM signal, continuous, or intermittent), an increase in oxidative DNA damage, ROS production, and autophagy activity was observed in GC-2 cells at the highest SAR dose of 4 W/kg [164,169–171]. Hence, there is evidence that the increase in ROS production does not occur immediately but with increasing exposure time (>12 h) or cumulative dose [170]. Nevertheless, an increase in mitochondrial superoxide production was observed in the same cell line after 2–6 h of exposure to unmodulated 1.8 GHz RF-EMF at lower doses (SAR: 0.15 W/kg), accompanied by lipid peroxidation [172]. In this comprehensive study, these observations were confirmed in GC-1 cells and freshly isolated spermatogonia, and the origin of observed RF-EMF effects was attributed to the mitochondrial respiratory chain. Even at higher exposure intensities (SAR: 1.5 W/kg), no increase, but rather a decrease, in mitochondrial ROS formation and no change in global ROS and lipid peroxidation levels were measured in mouse spermatozoa [172]. Hence, the mouse sperm reacted differently to RF-EMF exposure than the preliminary stages of sperm development, represented by the GC-1 and GC-2 cells. The exposed sperm cells exhibited indications for oxidative DNA damage and reduced quality despite the lack of indicators of oxidative stress.

Additional evidence for an influence of RF-EMF on reproduction was obtained from studies in Leydig cells from mice, in which exposure to a 1.8 GHz GSM signal (SAR: 0.116 W/kg) or a 1.95 GHz RF-EMF (SAR: 3 W/kg) led to reduced testosterone production [173,174]. While there was evidence for oxidative stress (i.e., CAT and MDA) [173] after a short exposure for 1–3 h, an increased ROS formation was not detected after the 24 h of exposure [174]. Lastly, effects on a model system for female reproduction were investigated in cultured murine preantral follicles upon developmental induction. The exposure to 2.45 GHz RF-EMF (SAR: 0.77–0.88 W/kg) for 1 h/day negatively affected the growth and development of follicles, which was associated with increased lipid peroxidation and oxidative stress markers [175].

5.3. Assessment of EMF Effects on Reproduction and Fertility

The influence on fertility and the development of fetuses is an important topic, as developing organisms and cells are particularly sensitive to external stress factors. Effects of EMF on reproduction, predominantly after RF-EMF exposure, were studied in male reproductive organs and sperm and their precursor stages. In addition, dams were exposed to EMF, and possible damage in early and late stages of pregnancy, as well as in the offspring, was investigated [51,112,159].

The majority of the findings from the animal studies indicate a functional and morphological impairment of testes and spermatozoa by EMF exposure (predominantly for RF-EMF), which was associated with an increase in ROS, a reduction in the antioxidative capacity, and lipid peroxidation [48,55,146–151,153,154]. A previous insult or pre-existing disease (i.e., diabetes) was shown to be a risk factor that enhanced oxidative stress, which could not be compensated for [158]. After in utero exposure, age-dependent effects on oxidative stress markers were seen in the offspring, differing, depending on the assessed organ system [160,161]. A study on impairments at early stages of pregnancy revealed indications of reduced blastocyst implantation [118].

In cell studies, mainly male germ cells and cells from male reproductive organs were used. These are very temperature-sensitive and, therefore, temperature fluctuations must be excluded during irradiation; otherwise, false-positive findings influence the evaluation [114,115]. This was not the case in many cell studies and, therefore, it cannot be excluded that some findings are false-positive. Overall, the few cell studies do not provide any reliable evidence for an impairment of sperm cells and their precursors by EMF-induced oxidative stress, although some of them reported indications for ROS formation and oxidative stress [164,169–172].

6. Further Observations of Oxidative Stress Induced by EMF

In addition to the extensive literature on effects of EMF on the nervous, immune, and reproductive systems, a number of studies on oxidative stress in other organ system and cell types have been published (Supplementary Materials, Tables S1–S4).

6.1. Oxidative Influences on Other Organs

Evidence of adaptation to oxidative stress and antioxidant processes induced by 900 MHz RF-EMF exposure (2.5 mW/cm^2) for 1 h/day was found in the liver and kidney of male Sprague-Dawley rats. ROS formation was increased in both organs after 60 days of RF-EMF exposure, which was associated with changes in markers of liver and kidney function. However, these changes were no longer present after 30 days of regeneration, indicating adaptation [35]. Examinations of oxidative stress in the liver of adolescent

Sprague-Dawley rats after 900 MHz RF-EMF (SAR: 0.0096 W/kg) exposure for 1 h/day during postnatal days 35–59 did not result in a significant induction of ROS but led to some changes in oxidative stress markers [176]. In contrary, analyses of liver tissue at postnatal day 60 showed changes in ROS, oxidative stress markers, and tissue toxicity after in utero exposure to a 1.8 GHz (SAR: 0.12 W/kg) for 20 days and 6, 12, 24 h/day [177]. RF-EMF exposure (950 MHz) of rats, dams, and their offspring of different ages (neonates up to 30 days after birth) for up to 51 days resulted in some changes in oxidative stress and DNA damage in the liver. These effects were dependent on age, exposure duration, and dose (whole-body SARs: 0.51, 0.18, 0.18, and 0.06 W/kg for neonates, day 6, day 15, and day 30 after birth, respectively) [178]. Reduced lipid peroxidation was found only in the neonates, after RF-EMF exposure in utero, while no differences between groups were observed for protein oxidation and CAT. DNA damage was only increased in 30 day old exposed animals while it was reduced in 15 day old animals. Thus, the results on DNA damage are inconclusive and might be random due to a large variability.

Whether a pre-existing condition or disease, such as diabetes, influences the extent of oxidative stress or modulates its defense was investigated in male Sprague-Dawley rats in a diabetes model [179]. Rats with diabetes, when compared to healthy rats, showed a more pronounced production of ROS and increased lipid peroxidation in the liver after 28 days of 900 MHz RF-EMF exposure (E-field: 25 V/m) for 4 h/day. Unfortunately, no SAR value was reported in this study, and the observation of diverging activity of SOD and CAT is somewhat counterintuitive as both are markers for the antioxidative defense [179]. In the study by Esmekaya et al., lipid peroxidation and NO production were increased in the liver, as well as in the lung, heart, and kidney, of male rats after exposure to pulsed 900 MHz RF-EMF (whole-body SAR: 1.2 W/kg) for 2 h/day for 3 weeks, whereas GSH levels were decreased [150]. Shahin et al. reported changes in ROS and the oxidative stress markers SOD, CAT, and GST in the liver and kidney of pregnant Parkes mice exposed for 45 days to 2450 MHz RF-EMF (SAR: 0.023 W/kg) [118]. The same group found an increase in ROS and associated indications for oxidative stress in the liver and kidney of male Swiss mice exposed to 2450 MHz RF-EMF (SAR: 0.018 W/kg) for 30 days [55].

Increased lipid peroxidation, as well as a decrease in antioxidative markers, was observed in the kidney of rats exposed to 217 Hz-pulsed 900, 1800 MHz, or 2450 MHz RF-EMF (whole-body SAR: 0.18 W/kg; 10 V/m) for 5 days/week and 60 min/day from in utero until 6 weeks after birth [160]. Interestingly, lipid peroxidation was decreased in exposed animals at the fourth week of life, while the antioxidative biomarkers were consistently lower than those of the corresponding controls at all three time-points assessed (4, 5, and 6 weeks after birth). Applying a 2450 MHz RF-EMF, a study in Wistar rats found changes in both ROS and oxidative stress markers in the kidney [180], while no alterations were found for ROS [181]. Similarly, four studies examining oxidative stress in the kidney of Sprague-Dawley rats using 900 MHz RF-EMF signals yielded ambivalent results. Two of them reported changes in ROS formation, oxidative stress, and tissue toxicity [35,182], one demonstrated increased ROS, tissue toxicity, and apoptosis without assessing antioxidative markers [183], and one found no indication for oxidative stress although seeing kidney toxicity [184]. Other investigations in the kidney revealed changes in ROS, oxidative stress, tissue toxicity, and apoptosis, applying 2.1 GHz RF-EMF [185].

In the heart of Wistar rats, 2.45 GHz RF-EMF exposure for 5 min (50, 100, 150, 200 mW/cm^2) or 30 days (SAR: 0.1 W/kg) resulted in changes in ROS and oxidative stress markers and increased tissue toxicity and apoptosis [186] or in more lipid peroxidation and reduced SOD, respectively [187]. Two studies in Sprague-Dawley rats examined oxidative stress in the heart applying laboratory-generated 900 MHz RF-EMF signals. After in utero exposure during gestational days 13–21 at 0.025 W/kg SAR for 1 h/day and examination at postnatal day 21, there were clear indications of oxidative stress, tissue toxicity and apoptosis in the heart [188]. In another study using young rats, increased ROS and increased apoptosis but no changes in antioxidative defense or tissue toxicity were found after 900 MHz RF-EMF exposure (SAR: 0.0093 W/kg) for 1 h/day on postnatal days 21–59 [189].

Lastly, there are some sporadic reports about oxidative stress related to RF-EMF exposure in other tissue types. For instance, 2.45 GHz WiFi exposure (whole-body SAR: 0.1 W/kg) of male Wistar rats caused increased lipid peroxidation in the mucosa of the vocal tract, while no differences in antioxidative biomarkers were measured [190]. Increased lipid peroxidation, apoptosis, and pathological tissue changes were found in the bladder of young rats exposed to 900 MHz RF-EMF (SAR: 0.0067 W/kg) [183]. Two animal studies on possible oxidative stress on the eyes have been published [119,191], both indicating no increased ROS production. Exposure to 2.45 GHz RF-EMF, pulsed at 217 Hz (whole-body SAR: 0.1 W/kg), for 1 h/day and 30 days had no marked effect on lipid peroxidation in the eye, while antioxidative biomarkers (GPx and GSH) were significantly decreased [191]. In combination with melatonin treatment, these effects were reverted, which was explained by the antioxidant effect of melatonin. In contrast, no evidence for increased oxidative stress and NO production by 1.8 GHz RF-EMF (whole-body SAR: 0.4 W/kg) was found in Wistar rats exposed 1 h/day for 3 weeks [119]. However, the exposure of animals in the cages was performed using a cell phone in talk mode, which is inevitably associated with large uncertainty and variability of the SAR.

For ELF-MF exposure, only a few animal studies with readout concerning oxidative stress have recently been published. No evidence for increased lipid peroxidation (MDA) in the liver was found by Erdal et al., in which Wistar rats of both sexes were exposed to 50 Hz ELF-MF (1 mT) for 4 h/day and 445 days [192]. The results of a study in male Wistar rats exposed to 60 Hz ELF-MF (2.4 mT) for 2 h indicated an impairment of the antioxidant defense in the heart and kidneys [193]. However, rats kept in tubes of a carrousel setup for exposure without ELF-MF showed similar levels of ROS and antioxidative markers, indicating that the stress situation caused by a containment in tubes also triggered oxidative stress. These findings demonstrate the need for appropriate sham-exposure controls for such experimentations to exclude confounding factors resulting in oxidative stress. However, this study did not indicate whether the animals were previously trained to go into the tubes to exclude this stress factor.

6.2. Experimental Data on the Effect of EMF on Skin, Epithelial, and Cancer Cells

Because of their function as a barrier and first line of defense against the environment, skin and epithelial cells are of interest for possible EMF effects. However, only experimental studies with cultured cells and none with animals have been performed in the last decade. A number of cell types with different functions and properties were used such as fibroblasts from the skin of rats (Rat-1), mice (NIH/3T3, McCoy), and humans (HSF) or human gingival fibroblasts. In addition, there are experimental data from human keratinocytes (NCTC-2544, HaCaT), specialized epithelial cells of the mammary gland (MCF10A), pulmonary fibroblasts from human (IMR-90, MRC-5) and hamster (V79), Chinese hamster ovary cells (CHO), cells of the human retina (RPE-1), and lens (HLE-B3) of the eye and human amniotic cells (FL, HTR-8/SV40neo).

Due to the use of a wide range of cell types and the limited number of directly comparable studies, the current picture regarding the effects of EMF exposure on skin and epithelial cells is patchy. Nevertheless, there is some evidence that EMF can lead, at least temporarily, to an increase in ROS production and oxidative stress in these cell types, whereby the majority of the data originate from cell studies in the ELF-MF range. A transient increase in ROS was observed in human keratinocytes (NCTC-2544) and in mouse embryonic fibroblasts (MEF) upon continuous exposure to 50 Hz ELF-MFs [194,195]. In keratinocytes, an increase in ROS formation was found after 1–2 h of exposure, concurrent with changes in oxidative stress markers (GSH, GPx, SOD) [194]. After 4 h of exposure, ROS measurements no longer showed any differences to control cells, but there were signs of building up the antioxidative defense. It is also remarkable that this exposure-related increase in ROS was found at low (50 and 100 μT) but not at higher field strengths, i.e., not in the range used in many other studies.

Nevertheless, increased ROS formation was also found in mouse fibroblasts after exposure to an ELF-MF (2 mT) in a time window of 2–6 h, correlating with an increase in autophagy [195]. As the exposure period progressed, the cells adapted to the exposure and no longer reacted with increased ROS production. In IMR-90 pulmonary fibroblasts exposed to strong 60 Hz ELF-MF (6 mT) for 3 days, this prolonged exposure even led to reduced ROS formation [196]. Together with fluctuations of antioxidative markers, a transient reduction of superoxide, H_2O_2, and NO level was reported for MRC-5 lung fibroblasts daily exposed for 1 h to strong 50 Hz ELF-MF (10 mT) for days 1–3, while a prominent increase was found after 7 days [197]. In the context of investigating the influence of 50 Hz ELF-MF on processes of wound healing and inflammation, a similar exposure duration (3–6 h) in gingival fibroblasts and in HaCaT keratinocytes showed increased iNOS expression and activity, whereas CAT activity and superoxide formation were reduced [198,199]. Similar observations were made in two other cell types, breast (MCF10A) and retinal epithelial cells (RPE-1), in which no signs or even a tendency to reduced oxidative stress were observed after ELF-MF exposure [200,201]. However, some of the measurements were performed after a longer recovery period and, therefore, presumably do not represent direct effects of exposure but rather a secondary cell response.

One research group conducted a series of studies in FL cells derived from the epithelium of the amniotic sac [202–205]. They found a slight increase in ROS in the cytoplasm and, with some delay, superoxide production in the mitochondria in the time period of 5–30 min after the beginning of exposure to a 50 Hz ELF-MF (0.4 mT) exposure [202]. In this case, however, it is likely that the exposure led to the activation of cellular signaling pathways rather than to canonical oxidative cell stress [203–205]. For instance, ELF-MF exposure alters the activity/excitability of epidermal growth factor (EGF) receptors in the cell membrane, thereby remodeling the MAPK pathway and subsequent cell responses.

The function of EMF-induced production of radicals as signal molecules for the activation of the MAPK signaling pathway was previously postulated for RF-EMF in a pioneering study [206]. In Rat-1 rat skin fibroblasts, a short exposure to unmodulated 875 MHz RF-EMF stimulated NADH oxidase and ROS production, thereby increasing the sensitivity of the EGF receptor and activating the MAPK pathway. Applying RF-EMF, there is further evidence of transient ROS formation and oxidative stress provided by a few studies. In murine NIH/3T3 embryonic fibroblasts, an increase in ROS was found, most pronounced after exposure to a 1.8 GHz GSM signal (SAR: 2 W/kg, 5/10 min on/off) for 1–2 h or a combination of a 837 Hz GSM and a 1.95 GHz UMTS signal (SAR: 4 W/kg) [102,207]. In contrast, the combined exposure to these two signals in MCF10A breast epithelial cells did not result in an increase in ROS and changes in oxidative stress markers [208]. Likewise, no increase of mitochondrial superoxide formation was observed for exposure to 1.8 GHz RF-EMF (SAR: 0.15 W/kg) for 2–6 h in another mouse fibroblast cell line [172]. Thus, the temporary increase in ROS does not seem to be a general cell response but specific to certain cell types.

Performed again in mouse fibroblasts, an unusually high cell mortality was found upon continuous 1.8 GHz RF-EMF exposure (1.2 W/m^2) for 2 days [105]. In contrast to most other comparable investigations, ROS formation was not temporary and detectable shortly after the start of exposure, instead it became obvious only after 6 h and increased with exposure duration. This finding suggests that ROS formation might not be a direct result of exposure but a secondary effect, due to apoptosis. Similar mechanisms may have played a role in the ROS increase after exposure of CHO cells to a GSM-modulated 900 MHz RF-EMF (SAR 2 W/kg) for 12 and 24 h [209]. This notion is further supported by observations made in hamster (V79) and human (HSF) fibroblasts. Without having a negative effect on viability or leading to cell damage, exposure to 1.8 GHz RF-EMF (SAR: 1.6/3 W/kg, GSM signal or carrier wave) led to an early transient increase in ROS formation which ceased after 24 h of exposure [113,210,211]. In accordance with these conclusions, no evidence for oxidative DNA damage was found in pulmonary fibroblasts, regardless of the exposure duration (1, 4, 24 h) with different doses (SAR: 0.5, 2, 4.9 W/kg) and modulations of 1.95 GHz RF-EMFs (GSM, UMTS, WiFi) [212]. However, a slight reduction in cell vitality after 6–24 h of exposure to a 1.8 GHz GSM signal (SAR: 2.3 and 4 W/kg) was observed in HLE B3 lens epithelial cells, accompanied by an increase in the lipid peroxidation marker, MDA [213]. Gene expression and protein levels for key antioxidative enzymes (SOD, CAT, GPx1) were lowered. Hence, the authors concluded that the higher ROS levels measured after 30–90 min of exposure were due to a reduced activity of the antioxidant defense system, which is in contrast to other cell types, in which ROS production was attributed to stimulation of oxidizing enzymes such as the NADH oxidases by EMF.

In addition to the studies with cultured cells that could be assigned to one of the above biological functions or organs, there are also some experimental results that were generated in various primary or tumor cells of different origin. Although it is hardly possible to derive a uniform picture and comprehensive conclusions, these results provide additional information about the influence of EMF on the oxidative balance of cells. For instance, 50 Hz ELF-MF (100 μT) did not cause any change in ROS formation or GSH levels in heart muscle cells, whether after continuous or after interval exposure for a short time [214]. In contrast, in a murine squamous cell carcinoma line (AT478), exposure at 1 mT for 16 min resulted in an increase in ROS formation and in the activities of SOD and GPx, while MDA concentrations decreased [215]. However, other cancer cell lines reacted differently to 50 Hz ELF-MF exposure (6 mT) for 2 h. ROS levels remained unchanged in Gist-T1 gastrointestinal stromal tumor cells, increased in HCT-116 colorectal cancer cells, and tended to be lower in HEK293T embryonic kidney cells [201]. Continuous 60 Hz ELF-MF exposure (6 mT) of the HeLa cervical cancer cells resulted in lower ROS and better cell viability [196], whereas, in breast cancer cells, an increase in ROS formation after 2 h was found, accompanied by induced apoptosis upon prolonged exposure to the ELF-MF (1 mT) [216]. Notably, ROS formation after exposure to 200 Hz rather than 50 Hz ELF-MF was considered here, as the former generally showed stronger effects on apoptosis.

In the RF-EMF range, analogous observations were made in MDA-MB-231 breast cancer cells exposed to a 900 MHz GSM-like signal (SAR: 0.36 W/kg). RF-EMF exposure for 1 h resulted in an increase in ROS formation and induced cell death [217]. Apoptosis and more ROS was also seen in MCF-7 breast cancer cells after exposure to 217 Hz pulsed 900, 1800, and 2450 MHz RF-EMF (average SAR: 0.36 W/kg) for 1 h [111]. RF-EMF-induced cell death was also observed in embryonic kidney cells (HEK293, HEK293T) exposed to an unmodulated 940 MHz carrier wave (SAR: 90 mW/kg) [218] or 2.45 GHz (E-field: 2 V/m) [219,220] for about 1 h. However, the results from the analyses of the markers for oxidative stress differed. While the 2.45 GHz RF-EMF resulted in higher MDA levels and reduced activities of SOD and GPx, exposure to the 940 MHz RF-EMF decreased MDA values over time while increasing SOD, with maximal changes observed at 30–45 min after the exposure started. In similar time windows, a transient increase in ROS formation, accompanied by changes in oxidative stress markers, was reported after exposure of HEK293 cells to 940 MHz RF-EMF (SAR: 90 mW/kg) [218] or MC3T3-E1 osteoblastic cells to a 2.45 GHz WiFi signal (SAR: 0.16/0.85 W/kg) [221]. The reason for a reduction in cell numbers may not always be induced apoptosis but could result from the promotion of cell senescence [222]. This was observed in the population of various cancer cells, as well as in stem cells from adipose tissue, after exposure to a 1.7 GHz long-term evolution/fourth generation (LTE) signal (SAR: 1 and 2 W/kg) for 3 days. Depicted for HuH7 liver cancer cells and the adipose stem cells, the increased formation of mitochondrial and total ROS by exposure played a role in the promotion of senescence, as more cells with stronger ROS signals were present. On the other hand, exposure to 900 MHz RF-EMF (SAR: 80 or 170 mW/kg) in isolated thyroid cells neither affected cell vitality nor provided indications for oxidative stress or an increase in ROS formation [223].

In summary, EMF exposure of cultured cells does not to induce an universal cellular reaction, but a variety of mechanisms and stress responses including ROS formation and oxidative stress might be triggered, depending on cell type and experimental conditions. In this regard, it needs to be noted that established cell lines and especially cancer cells, representing the majority of the cell lines studied, might react more strongly and more variably than normal cells, likely attributed to their altered metabolism and regulatory mechanisms.

7. Conclusions

The majority of recent animal studies on increased ROS production and oxidative stress caused by EMF were aimed at investigations of the nervous system and reproduction. Analogously, in cell studies, neurons or neuron-like cells were most frequently used. Animal studies on oxidative stress and possible impairment of reproduction at different stages (sperm maturation, very early stages of pregnancy such as implantation, and effects in newborns and after a few weeks of EMF exposure to the mother animals during pregnancy) follow in second place. These animal studies were supported by some cell studies, mainly in mouse cell lines of the male reproductive system and in sperm. Overall, more cells than animal studies were published, using, in addition to the abovementioned cell types of the nervous and reproductive system, immune and cancer cells, as well as isolated cells from the skin and epithelia. For this report, animal and cell studies were included, according to their quality and research question, in order to give an informative overview of the available studies; however, this is not a systematic review.

In summary, indications for increased oxidative stress caused by RF-EMF and ELF-MF were reported in the majority of the animal studies and in more than half of the cell studies. Investigations in Wistar and Sprague-Dawley rats provided consistent evidence for oxidative stress occurring after RF-EMF exposure in the brain and testes and some indication of oxidative stress in the heart. Observations in Sprague-Dawley rats also seem to provide consistent evidence for oxidative stress in the liver and kidneys. In mice, oxidative stress induced by RF-EMF was predominantly demonstrated in the brain and testes, as well as in liver, kidneys, and ovaries. These observations were made with a variety of cell types, exposure times, and dosages (SAR or field strengths), within the range of the regulatory limits and recommendations. Certainly, some studies were subject to methodological uncertainties or weaknesses or are not very comprehensive regarding exposure time, dose, number, and quantitative analysis of the biomarkers used, to name a few. A trend is emerging, which becomes clear even when taking these methodological weaknesses into account, i.e., that EMF exposure, even in the low dose range, may well lead to changes in cellular oxidative balance. Organisms and cells are able to react to oxidative stress, and many observations after EMF exposure point to an adaptation after a recovery phase. Adverse conditions, such as diseases (diabetes, neurodegenerative diseases), compromise the body's defense mechanisms, including antioxidant protection mechanisms, and individuals with such pre-existing conditions are more likely to experience health effects. The studies show that very young or old individuals can react less efficiently to oxidative stress, which of course also applies to other stressors that cause oxidative stress. Further investigations under standardized conditions are necessary to better understand and confirm these phenomena and observations.

(animal studies); writing—review and editing, D.S. and M.M.; project administration, D.S. and M.M.; funding acquisition, D.S. and M.M. All authors read and agreed to the published version of the manuscript.

Funding: This research was partly funded by the Federal Institute of the Environment (FOEN), Switzerland. The APC was funded by the University of Bern.

Acknowledgments: We are grateful to Christopher Portier and Bettina Freymüller for critical reading and editing of the manuscript. We appreciate the suggestions of the anonymous reviewers helping to improve the manuscript. We note that a short report was generated and published on the webpage of the FOEN (https://www.bafu.admin.ch/bafu/en/home/topics/electrosmog/newsletter-of-the-swiss-expert-group-on-electromagnetic-fields-a.html, accessed on 21 January 2021) on the basis of the data and conclusion in this review.

Conflicts of Interest: The authors declare no conflict of interest. The funders had no role in the collection, analyses, or interpretation of data, in the writing of the manuscript, or in the decision to publish the results.

Abbreviations

8-OHdG	8-Oxo-2′-deoxyguanosine, 8-oxo-G
AC	Alternating current
ATRA	All-*trans* retinoic acid
CAT	Catalase
ELF-MF	Extremely-low-frequency magnetic field
EMF	Electromagnetic field
eNOS	Endothelial nitric oxide synthase
ERK	External signal-regulated kinase
GPx	Glutathione peroxidase
GSH	Glutathione
GSM	Global system for mobile communications, 2G
GSSG	Glutathione disulfide
GST	Glutathione *S*-transferase
GR	Glutathione reductase
HSC	Hematopoietic stem cell
IARC	International Agency for Research on Cancer
iNOS	Inducible nitric oxide synthase
LPS	Lipopolysaccharide
LTE	Long-term evolution, 4G
MAPK	Mitogen-activated protein kinase
MDA	Malondialdehyde
NADPH	Nicotinamide adenine dinucleotide phosphate
nNOS	Neuronal nitric oxide synthase
NO	Nitric oxide
NOS	Nitric oxide synthase
NOX	NADPH oxidase
PMA	Phorbol-12-myristate-13-acetate
PRDx	Peroxiredoxin
RF-EMF	Radiofrequency magnetic field
ROS	Reactive oxygen species
SAR	Specific absorption rate
SOD	Superoxide dismutase
TRPV1	Transient receptor potential cation channel subfamily V member 1
UMTS	Universal mobile telecommunications system, 3G
UV	Ultraviolet
WiFi	Wireless Fidelity, WLAN standard

Millimeter (MM) wave and microwave frequency radiation produce deeply penetrating effects: the biology and the physics

https://doi.org/10.1515/reveh-2020-0165
Received December 11, 2020; accepted April 28, 2021;
published online May 26, 2021

Abstract: Millimeter wave (MM-wave) electromagnetic fields (EMFs) are predicted to not produce penetrating effects in the body. The electric but not magnetic part of MM-EMFs are almost completely absorbed within the outer 1 mm of the body. Rodents are reported to have penetrating MM-wave impacts on the brain, the myocardium, liver, kidney and bone marrow. MM-waves produce electromagnetic sensitivity-like changes in rodent, frog and skate tissues. In humans, MM-waves have penetrating effects including impacts on the brain, producing EEG changes and other neurological/neuropsychiatric changes, increases in apparent electromagnetic hypersensitivity and produce changes on ulcers and cardiac activity. This review focuses on several issues required to understand penetrating effects of MM-waves and microwaves: 1. Electronically generated EMFs are coherent, producing much higher electrical and magnetic forces then do natural incoherent EMFs. 2. The fixed relationship between electrical and magnetic fields found in EMFs in a vacuum or highly permeable medium such as air, predicted by Maxwell's equations, breaks down in other materials. Specifically, MM-wave electrical fields are almost completely absorbed in the outer 1 mm of the body due to the high dielectric constant of biological aqueous phases. However, the magnetic fields are very highly penetrating. 3. Time-varying magnetic fields have central roles in producing highly penetrating effects. The primary mechanism of EMF action is voltage-gated calcium channel (VGCC) activation with the EMFs acting via their forces on the voltage sensor, rather than by depolarization of the plasma membrane. Two distinct mechanisms, an indirect and a direct mechanism, are consistent with and predicted by the physics, to explain penetrating MM-wave VGCC activation via the voltage sensor. Time-varying coherent magnetic fields, as predicted by the Maxwell–Faraday version of Faraday's law of induction, can put forces on ions dissolved in aqueous phases deep within the body, regenerating coherent electric fields which activate the VGCC voltage sensor. In addition, time-varying magnetic fields can directly put forces on the 20 charges in the VGCC voltage sensor. There are three very important findings here which are rarely recognized in the EMF scientific literature: coherence of electronically generated EMFs; the key role of time-varying magnetic fields in generating highly penetrating effects; the key role of both modulating and pure EMF pulses in greatly increasing very short term high level time-variation of magnetic and electric fields. It is probable that genuine safety guidelines must keep nanosecond timescale-variation of coherent electric and magnetic fields below some maximum level in order to produce genuine safety. These findings have important implications with regard to 5G radiation.

Keywords: 5G modulating pulses; coherent electronically generated EMFs; EMF pathophysiological and therapeutic effects; increased [Ca2+]i and calcium signaling; modulating pulses and biological EMF effects; penetrating effects via time-varying magnetic field penetration.

Introduction

Electronically generated electromagnetic fields (EMFs) are highly coherent, being generated at specific frequencies, with specific vector direction, with a specific phase and specific polarity. The special physics properties of such coherent EMFs have been discussed [1–5]. Similarly, biological impacts of coherent EMFs have also been discussed [6–10]. Such coherent EMFs generate much stronger electrical forces and magnetic forces than do natural incoherent EMFs. Most but not all natural EMFs are incoherent. The much stronger forces produced by electronically generated EMFs are of great importance with regard to EMF causation of biological effects and also with respect to our ability to use such EMFs for wireless communication. A study where coherence is central to wireless communication is the article of Geffrin et al. [5] which discusses many examples where coherence is essential for wireless communications and also discusses how antenna design is greatly influenced by the need to maintain such coherence. The biological importance of coherence was discussed in two contexts by Panagopoulos et al. [9]. The coherence of the polarity is required for maximum force generation. In addition, the coherence of phase is also important because identical phase produces constructive interference and supra-additive effects, whereas phase shifts lead to high amounts of destructive interference and much lower effects [9]. Golant [7] discusses how coherent MM-wave EMFs may produce resonance interactions with specific biological targets. Strong electrical forces produced by coherent electronically generated EMFs are an important feature of the Fröhlich [6] theoretical model of biological activity of EMFs. While it is clear from this, that there is a substantial literature that electronically generated EMFs are coherent and that such coherence is important for their acting in wireless communication and in producing non-thermal biological effects, this literature is not widely known nor is its importance appreciated among the vast majority of scientists studying EMF effects.

EMF propagation in a vacuum or in very low dielectric constant media, such as air, is characterized by a fixed relationship between the electric field and the magnetic field, as described by Maxwell's equations [11]. However electric fields are much more susceptible to absorption than are magnetic fields by many media, producing a breakdown of that fixed relationship (Keller and Karal [2]). Because the dielectric constant of intracellular and extracellular biological aqueous phases is estimated to be about 120 [12], such differential absorption is relevant to the issue of biological effects. However, as also discussed in ref. [2], the magnetic field penetration is determined by the magnetic field permeability which in essentially all biological tissues is very high, producing very high magnetic field penetration. Strong absorption of electric fields but not magnetic fields are found with MM-wave or microwave radiation traversing biological tissues and also many other media including building materials [13–15]. Electric field absorption is a function of both the dielectric properties of materials and also of the EMF frequency, such that the electric fields of MM-wave EMFs are almost completely absorbed in the outer 1 mm of the body, as shown in ref. [13–15]. The impedance of biological tissues is also likely to have roles in limiting electric field penetration. The rapid electric field absorption in biological tissues has lead telecommunications industry-associated and other scientists to predict that MM-wave biological effects will be limited to the outer 1 mm of the body and that lower microwave frequency effects, in the 400 MHz to 5 GHz range, are suggested to be limited to the outer 1–3 cm of the body. Various definitions are used to define microwave frequency radiation. In this paper, that term refers to 400 MHz to 5 GHz radiation, the range most commonly used for wireless communication.

Other scientists such as in many articles cited in Betskii and Lebedeva [16] have found deeply penetrating effects of MM-waves in human and animal bodies, but have interpreted these as possibly caused by effects near the surface of the body indirectly producing penetrating effects. Similar views are expressed in the Pakhomov et al. [17] review as follows: On p. 393, Pakhomov et al. [17] state that "The term millimeter waves (MMW) refers to extremely high frequency (30–300 GHz) electromagnetic oscillations. Coherent oscillations of this range are virtually absent from the natural electromagnetic environment." Further down [17] continues "Indeed, MMW have been reported to produce a variety of bioeffects, *many of which are quite unexpected from radiation penetrating less than 1 mm into biological tissues*" (italics added). It can be seen from this that although Pakhomov et al. [17] are aware that these MM-waves are coherent, they fail to consider that the MM-wave magnetic fields are highly penetrating and may, therefore, produce highly penetrating effects. On p. 400 of ref. [17], states that "It is clearly understood that MMW penetration into biological tissues is rather shallow, and any primary response must occur in skin or subcutaneous structures, or at the surface of the eye." This review will discuss towards its end, two distinct probable mechanisms by which highly penetrating time-varying MM-wave magnetic fields can produce highly penetrating effects reported in ref. [16, 17] and elsewhere.

Gaiduk [18] showed that when most of the water molecules are hydrogen bonded to solutes or when such solutes otherwise greatly determine water hydrogen bonding structures, as is often the case within living cells, the electric field absorption is lowered. This may be minor part of the mechanism leading to greater penetration of effects, shown below but time varying penetrating magnetic field effects are argued here to be much more important.

Penetrating effects of MM-wave and microwave radiation

Penetrating effects of non-thermal, non-pulsed, continuous wave MM-wave exposures have been reported in a large number of studies. Zalyobokskaya [19] reported that such exposures in rodents produced pathophysiological structural, functional and biochemical changes in each of the following internal organs: the brain, the myocardium, liver, kidney and bone marrow. These are each deeper in the body that 1 mm and therefore provide evidence for deeper MM-wave effects than the industry claims is possible.

Betskii and Lebedeva [16] reviewed large numbers of studies, both human and animal studies of highly penetrating nonthermal MM-wave effects. I will concentrate here on some of the human studies cited in that paper, although animal studies such as discussed in Zalyobokskaya [19] were also reviewed. When that review [16] was published, the voltage-gated calcium channel mechanism, discussed below, was not known so that their interpretation of the various findings discussed was very different from the interpretation discussed below.

We will be discussing here MM-wave effects impacting human brain function as well as a number of other penetrating effects of MM-wave radiation. References [20–24] each show that low intensity, non-thermal non-pulsed MM-wave EMFs produce changes in the EEGs in the human brain which are a measure of the electrical activity of the brain. The citations [21–24] each also find other neurological effects in addition to EEG effects are produced such MM-wave EMFs. The shortest path from outside the body into the human brain is through the skin, skull and meninges surrounding the brain, usually circa 6–7 mm in adults.

Such findings should not be surprising for two different reasons discussed in this paragraph and the following two paragraphs. Pikov et al. [25] and also Siegel and Pikov [26] at Caltech each find that stunningly low intensities of non-pulsed MM-wave EMFs produce strong impacts on brain derived neurons. Pikov et al. [25] in their abstract state that: "The applied levels of MMW power are three orders of magnitude below the existing safe limit for human exposure of 1 mW/cm^2. Surprisingly, even at these low power levels, MMWs were able to produce considerable changes in neuronal firing rate and plasma membrane properties. At the power density approaching 1 $\mu W/cm^2$, 1 min of MMW exposure reduced the firing rate to one third of the pre-exposure level in four out of eight examined neurons. The width of the action potentials was narrowed by MMW exposure to 17% of the baseline value and the membrane input resistance decreased to 54% of the baseline value across all neurons."

Consequently, Pikov et al. [25] are seeing large, repeated impacts on neuronal cell activity at exposure levels of 1 $\mu W/cm^2$, one one-thousandth of the normal safety guideline allowable levels. They are seeing large effects at exposure levels of 1/1,000th of allowable levels. Normally, safety guideline allowable levels are set at no more than 1% of the lowest level found to produce any effects. By that standard, safety guidelines for MM-wave radiation should be *more than* 100,000 times lower than the current safety guidelines. Siegel and Pikov [26] found effects at still lower level exposures, 300 mW/cm^2, which argues that safety levels should be *more than* 330,000 times lower than current safety guidelines. It should be noted that these are cells in culture, with no shielding from tissues above the cells, other than that produced by the culture medium. Each of the findings, discussed above, are effects produced by non-pulsed, continuous wave MM-wave EMFs, not the extraordinarily highly pulsed 5G radiation, which is predicted to have vastly stronger effects than do these non-pulsed MM-wave, continuous wave EMFs, as discussed below. The US FCC and other regulatory agencies are pushing to change safety guidelines to allow much higher exposures than currently allowed by the current safety guidelines!

There is a second reason why these MM-wave, brain-related findings are not surprising. Reference [27] cited multiple primary literature studies and also review articles which show that EEGs are influenced by low intensity, non-thermal microwave frequency EMFs and also cited many primary literature studies showing that such microwave frequency EMFs also produce widespread human neurological and neuropsychiatric effects. Reference [28] cited 15 review articles showing that such microwave frequency EMFs produce neurological/neuropsychiatric effects.

The remaining human highly penetrating MM-wave effects discussed here, from Betskii and Lebedeva review [16], are apparent therapeutic effects. There are genuine therapeutic effects produced by microwave and other frequency EMFs, so it should not be surprising to find that MM-waves can produce therapeutic effects. There are multiple studies reporting that non-thermal, non-pulsed MM-waves produce improved bone marrow function in humans [29–32]. Other therapeutic effects of MM-waves include increased healing of gastric and duodenal ulcers [33] and improved cardiac function [34, 35]. Two other types of penetrating effects documented by the Pakhomov et al. [17] review, will be discussed later in this paper.

The studies outlined in the previous paragraphs of this section, are all highly penetrating effects produced by non-thermal, non-pulsed MM-wave EMFs. 5G radiation, however, uses extraordinarily high levels of modulating pulses in order to carry extraordinarily high amounts of information per second [36]. Reference [28] cited 10 different reviews each showing that EMFs with modulating pulses produce, in most cases, much higher levels of biological effects than do non-pulsed (continuous wave) EMFs of the same average intensity. If follows that 5G may be predicted to produce very damaging highly penetrating effects because of its extraordinary level of modulating pulsation. The relationship between therapeutic effects and pathophysiological effects produced by EMFs is discussed below.

The recent publication of Kostoff et al. [37] came to similar conclusions to those stated in the previous paragraphs, that MM-waves produce highly penetrating effects: “These results reinforce the conclusion of Russell (quoted above) that *systemic results may occur from millimeter wave radiation*” (italics added). Continuing from ref. [37] “To re-emphasize, for Zalyubovskaya’s experiments, the incoming signal was unmodulated carrier frequency only, and the experiment was single stressor only. Thus, the expected real-world results (when human beings are impacted, the signals are pulsed and modulated, and there is exposure to many toxic stimuli) would be far more serious and would be initiated at lower (perhaps far lower) wireless radiation power fluxes.”

Much deeper effects than predicted by the industry are not limited to millimeter waves but also occur with microwave radiation. Microwave radiation, as discussed above, has been argued to produce effects limited to the outer 1–3 cm in the body. However, Hässig et al. [38, 39], in Switzerland, find that pregnant cattle grazing near a cell phone tower (also known as a mobile phone base station) produce large numbers of newborn calves with cataracts. The fetus’s deep location in the mother’s body should protect it from cell phone tower radiation but does not. Switzerland has safety guidelines for cell phone tower radiation that are 100 times more stringent than the U.S. or EU guidelines so that these are quite low intensity EMFs by most standards, but they produce effects very deeply in the mother’s body.

The rest of this paper focuses on how such highly penetrating effects can be produced. Both the biology and the physics are essential to this discussion.

The primary mechanism of action of low intensity EMFs in producing biological effects is activation of voltage-gated calcium channels (VGCCs) via its voltage sensor

The most important type of evidence for the EMF-voltage gated calcium channel (VGCC) activation mechanism, is that effects produced by EMF exposures can be blocked or greatly lowered by calcium channel blockers, drugs that are specific for blocking voltage-gated calcium channels [VGCCs) [12, 27, 28, 40]. Five different types of calcium channel blockers have been used in these studies, each of which is thought to be highly specific for blocking VGCCs [40]. Diverse EMFs produce effects which are blocked or greatly lowered by the calcium channel blockers, ranging from millimeter wave frequencies, microwave, radiofrequencies, intermediate frequencies, extremely low frequencies (including 50 and 60 Hz), all the way down to static electric fields and even static magnetic fields [12, 28, 40]. Following EMF exposure, the exposed cells and tissues have large, rapid increases in calcium signaling [12, 27, 28, 40], produced by increases in intracellular calcium [Ca2+]i levels. This overall interpretation has been confirmed by patch-clamp studies, studies using calcium-free medium, and studies measuring [Ca2+]i levels [28]. This mechanism has been widely recognized in the scientific literature with the first publication on this [40] being cited 305 times according to the Google Scholar database, at this writing. New scientific paradigms are usually only very slowly recognized in the scientific literature such that the widespread interest in and acceptance of this mechanism is very unusual. That does not, of course, mean that everyone accepts it.

The direct target of the EMFs is the voltage-sensor, which, in the normal physiology, controls the opening of the VGCCs in response to partial depolarization across the plasma membrane. Four distinct classes of VGCCs are activated in response to low level EMF exposures, L-type, T-type, N-type and P/Q-type VGCCs [40]. Voltage-gated sodium, potassium, and chloride channels, each controlled by a similar voltage sensor are also activated by low intensity EMF exposures, although these have relatively minor roles in producing effects compared with those of VGCC-produced [Ca2+]i elevation [28]. Plant TPC channel activation via a similar voltage sensor also produce plant calcium-dependent EMF effects [41]. Each of these channels is controlled by a similar voltage-sensor, suggesting that the voltage-sensor is the direct EMF target.

The electrical forces produced by even weak electronically generated EMFs on each of the 20 positive charges in the VGCC voltage sensor are thought to be very strong due each of three distinct mechanisms, which act multiplicatively: 1. Electronically generated EMFs are highly coherent, as discussed above, being emitted with a specific frequency, in a specific vector direction, with a specific phase and specific polarity. This high-level coherence causes the electrical and magnetic forces produced by these to be vastly higher than are forces produced by incoherent natural EMFs. 2. The electrical forces on these charges in the voltage sensor are thought to be approximately 120 times higher than forces on charges in the aqueous phases of our cells and bodies, as predicted be Coulomb's law, due to the difference of the dielectric constant in the two locations [12, 28]. 3. The forces on the charges in the voltage sensor are also thought, to be approximately 3,000 times higher because of the high electrical resistance of the plasma membrane and therefore the high level of amplification of the electric field across the plasma membrane [12, 28]. This helps us to understand how VGCCs and other voltage-gated ion channels can be activated by what are considered to be very weak EMFs. The important finding here is that EMFs activate the VGCCs and other voltage-gated ion channels not via depolarization of the plasma membrane but rather via the direct forces they produce on the circa 20 charges in the voltage sensor. One puzzle discussed in ref. [40] and also below in this paper is how can static magnetic fields activate the VGCCs when physics shows that static magnetic fields cannot put forces on static electrical charges. These magnetic field effects are discussed in the next section.

How then does EMF-produced VGCC activation produce biological effects? Our best understanding of this is outlined in Figure 1 [12, 28, 40]. The main pathophysiological effects seen going to the bottom of Figure 1, are produced through excessive calcium signaling produced by [Ca2+]i elevation and by the peroxynitrite pathway, with the latter involving increases in reactive free radicals, oxidative stress, NF-kappaB activity and inflammatory cytokine levels and also mitochondrial dysfunction. There is also a pathway by which VGCC activation, acting via increased nitric oxide (NO), NO signaling and Nrf2 stimulation can produce therapeutic effects that also helps explain EMF effects. The therapeutic pathway is thought to be produced by modest [Ca2+]i elevation whereas the pathophysiological pathways are produced by higher level [Ca2+]i elevation.

MM-waves have been shown to act via activation of the VGCCs and also voltage-gated potassium channels [42–44]. Therefore it seems likely that MM-waves act via such channel activation as do lower frequency EMFs. This interpretation is confirmed by findings that MM-waves raise [Ca2+]i levels, calcium signaling and also nitric oxide (NO) [42] (compare with Figure 1). It is also confirmed by findings that MM-waves raise peroxynitrite [45] and by findings, discussed above, that MM-waves can produce similar pathophysiological effects and therapeutic effects to those produced by lower frequency EMFs. There is an additional channel that is probably activated by MM-waves acting on voltage sensors, the Ca2+-activated potassium channel as shown by Geletyuk et al. [46]. It was shown in ref. [46] using patch-clamp studies, that closed Ca2+-activated potassium channels are opened by exposures to low intensity non-pulsed MM-waves. This same channel has also been shown to be activated by both 50 Hz and microwave frequency EMFs [47]. Ca2+-activated potassium channels have been shown to be activated by a voltage sensor similar in structure to the voltage sensors discussed above acting synergistically with increases in [Ca2+]i. It follows that EMFs may act to activate Ca^{2+}-activated potassium channels via the voltage sensor in that channel and also via the VGCC voltage sensors.

Can Nrf2 activation (see Figure 1) produce the therapeutic responses reported to occur following MM-wave exposures [16], as discussed in a previous section? Garkavi et al. [48] showed that MM-waves produced antistress responses and such antistress responses have been shown to be produced by therapeutic Nrf2 elevations (see, for example [49, 50]). Consequently, it is plausible that the therapeutic mechanism outlined in Figure 1 can produce the penetrating therapeutic effects, discussed above to be found following non-pulsed MM-wave exposures.

What mechanisms produce highly penetrating effects of MM-waves?

With the electrical parts of MM-wave radiation largely absorbed in the outer 1 mm of the body, how, can we get these highly penetrating effects through impacts on the voltage sensor of the VGCCs produced by these highly coherent electronically generated EMFs?

Two explanatory mechanisms are proposed here, each as a consequence of the very highly penetrating, time-varying magnetic forces produced by the highly coherent electronically generated EMFs including MM-wave EMFs. Let's consider each these two explanatory mechanisms, one at a time.

The discussion on Maxwell's equations in Wikipedia [11] states that "The Maxwell–Faraday version of Faraday's law of induction describes *how a time varying magnetic field* creates ('induces') an electric field" (italics added). Coherent highly penetrating time-varying magnetic fields will produce strong forces on ions dissolved in the aqueous phases in our bodies, moving those ions in both the extracellular medium and also in intracellular aqueous phases and therefore regenerating a highly coherent electric field similar to but of lower intensity to the original electric field of the EMF before entering the body. The regenerated EMF can, then act to put forces on the charges of the voltage sensor thus activating the VGCCs. The

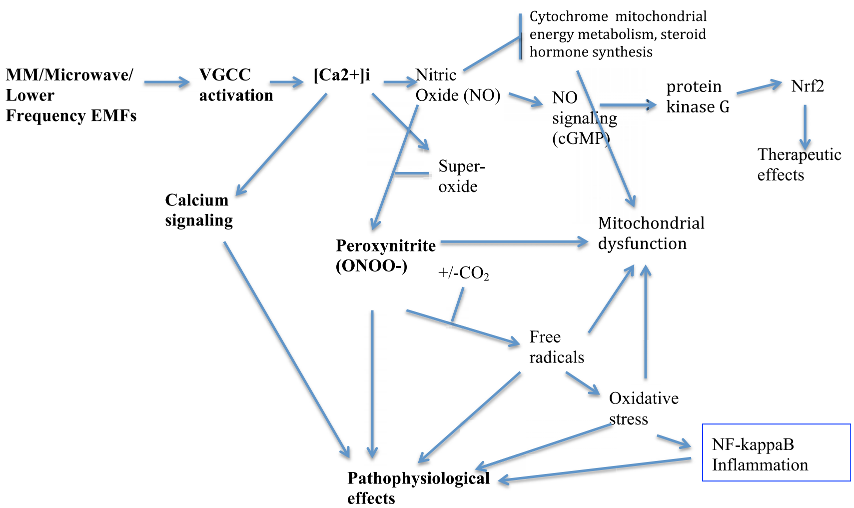

Figure 1: Diverse frequency EMFs act via activation of voltage-gated calcium channels (VGCCs) producing increased intracellular calcium [Ca2+]i. [Ca2+]i is defined as the calcium ion concentration in the cytoplasm which is distinct from the calcium concentration in the endoplasmic reticulum or the mitochondria, which are regulated separately. This leads to production of pathophysiological effects mainly via excessive calcium signaling and activation of the peroxynitrite/free radical/oxidative stress, NF-kappaB and inflammation pathway. Therapeutic effects are produced primarily via nitric oxide (NO) signaling leading to increased Nrf2 activity. Because the therapeutic pathway produces effects that are almost exactly opposite the effects produced by the peroxynitrite pathway, different EMF exposures may produce almost opposite effects. Copied from ref. [28] with permission.

physics here is essentially identical to the physics of electrical generation. In electrical generators, time-varying magnetic fields put forces on mobile electrons in copper wires, moving those mobile electrons and generating, in turn, an electrical current. In our bodies, the highly penetrating time varying magnetic fields put time-varying forces on dissolved mobile ions in aqueous phases in our bodies, generating a coherent electric field which can act on the voltage sensors to activate the VGCCs, as discussed above. A study providing support for this mechanism is the study of Deghoyan et al. [51] which found that non-thermal effects on cells in culture were produced through MM-wave irradiation of the medium surrounding these cells. This may or may not be the primary mechanism by which MM-waves produce highly penetrating effects.

There is second highly plausible mechanism by which highly penetrating magnetic fields can put forces on the charges in the voltage sensor activate voltage-gated ion channels. In ref. [40] it was shown that static magnetic fields also act, as do EMFs, via VGCC activation to produce biological effects that can be blocked with calcium channel blockers, so that the biological effects must have been produced via VGCC activation. Specifically, in Table 1 of ref. [40] and refs. [10], [12] and [24] in that paper each showed that effects produced by static magnetic fields can be blocked by calcium channel blockers, drugs specific for blocking VGCCs. Consequently, static magnetic fields produce effects via VGCC activation. That conclusion has been confirmed by the findings from patch-clamp studies, showing that static magnetic fields produced VGCC activation and also activation of voltage-gated sodium channels [52]. Those findings that static magnetic fields can act via the voltage sensor to activate VGCCs and apparently other voltage-gated ion channels created a puzzle that was discussed in ref. [40]. That puzzle is that static magnetic fields do not produce forces on static electrically charged objects. The answer to that puzzle, as discussed in ref. [40], is that the plasma membranes of cells are constantly moving and therefore the voltage sensors of the VGCCs located in the plasma membrane are also moving, so that static magnetic fields can produce time-varying forces on the charges of the VGCC voltage-sensor. These findings clearly raise the possibility that the highly penetrating time-varying magnetic fields derived from MM-wave or other frequency EMFs, including the extraordinarily high densities of modulating pulses of 5G, can have very high activity when acting directly on the 20 positive charges in the voltage sensor of the VGCCs to activate the VGCCs.

Both modulating EMF pulses and pure EMF pulses can act via each of the two mechanisms discussed here to produce large, very short term, penetrating changes in the forces on electrical charges including the voltage gated ion channel voltage sensor charges. Modulating and pure pulses inevitably produce vastly greater maximum time-variation and are, therefore, predicted to produce vastly greater maximum forces on the voltage sensor charges.

Because each of the two mechanisms proposed in this section for the generation of penetrating effects are dependent upon time-varying magnetic fields, together they provide a new understanding of the great importance of both modulating and pure pulsation in producing high level EMF effects.

Pakhomov et al. [17] reviewed findings with regard to non-pulsed MM-Waves: cardiac effects and electromagnetic hypersensitivity (EHS)

There are important findings on both animal cardiac effects and on animal tissue and human EHS-like effects produced by non-pulsed MM-wave exposures that were reviewed in Pakhomov et al. [17]. These are discussed here, in contrast, other MM-wave studies including those reviewed by Zalyobokskaya [19] and by Betskii and Lebedeva [16] which were discussed much earlier.

There are two important reasons for the author choosing to discuss the Pakhomov et al. [17] review on cardiac effects and also EHS-like effects here, as opposed to much earlier. Each of these require comparing animal studies with human studies. When highly penetrating MM-wave magnetic fields produce highly penetrating effects in animals and in humans, the difference in body size between humans and rodents is of little importance in predicting effects. A second reason for discussing these parts of ref. [17] here, is that the VGCC activation mechanism discussed above is predicted to be central to our understanding of both cardiac effects and EHS.

Chernyakov et al. [53], as discussed on p. 399 of ref. [17], reported on 990 experiments where very low intensity MM-wave EMFs changed the membrane function of the pacemaker cells of the sinoatrial node of the frog heart. In most cases, there was an almost instantaneous (less than 2 s) decrease in the interspike interval of these cells which in an intact heart would produce tachycardia. These occurred with intensity ranges of 20–500 $\mu W/cm^2$ and were, therefore, clearly non-thermal effects. Furthermore, as discussed on p.400 of ref. [17], Chernyakov et al. [53] showed that very low intensity MM-wave EMFs could produce changes in heart rate in anesthetized frogs, including both tachycardia (increase heartbeat) and bradycardia (slow heartbeat) and also arrhythmias. These also occurred when the hearts had been completely denervated although the severity of these changes decreased with denervation. The studies in this paragraph show that low intensity MM-wave EMFs produce direct effects on the membrane activity of the pacemaker cells in the sinoatrial node of the frog heart, influencing the heartbeat, but that the responsiveness of these cells can be influenced by neurological activity.

Other important cardiac studies of low intensity MM-waves were reported by Potekhina et al. [54] in the rat. They [54] showed that MM-waves produced changes in heartbeat including arrhythmias, tachycardia and bradycardia. Longer term (circa 3 h) exposures produced large numbers of animals who died of apparent sudden cardiac death. It is the author's opinion that most if not all of these EMF cardiac effects are produced by the direct impacts of diverse EMFs impacting the pacemaker cells in the sinoatrial node of the heart. One additional set of observations supporting that view are the findings of Liu et al. [55] showing that pulsed microwave EMFs produce heart failure-like changes in the sinoatrial node of the heart. The reason the pacemaker cells of the sinoatrial node of the heart may be particularly sensitive to EMFs is because they contain particularly high densities of T-type VGCCs, with both T-type and L-type VGCCs having essential roles in producing the pace making activity [56, 57]. These findings suggest that penetrating EMF effects can produce commonly observed cardiac effects via direct impacts on the pacemaker cells in the sinoatrial node of the heart.

Pakhomov et al. [17] also reviewed findings showing that non-pulsed MM-wave EMF exposures produce EHS-like effects in animal nerve tissue, and in humans. EHS is characterized by long term sensitivity responses to electromagnetic or electric fields [17] describes three studies where non-pulsed MM-wave exposures produced fairly long-term sensitivities in animal tissues and three additional studies of long term neurological/neuropsychiatric sensitivity in humans.

Burachas and Mascoliunas [58] described changes in the compound action potential (CAP) in the frog sciatic nerve following MM-wave exposures. They found that "CAP decreased exponentially and fell 10-fold within 50–110 min of exposure at 77.7 GHz, 10 mW/cm^2. CAP restored entirely soon after exposure, but the nerve became far more sensitive to MMW. CAP suppression due to the next exposures became increasingly steep and finally took only 10–15 min. This sensitized state persisted for at least 16 h" CAP is a measure of the overall electrical activity of the nerve. These findings may be interpreted in terms of MM-wave EMF exposures producing long-term EHS-like sensitivities in the frog sciatic nerve.

A second study by Chernyakov et al. [53] also reported sensitivity changes using a different frog nerve and also different MM-wave exposure protocols. “The exposures lasted 2–3 h, either with a regular frequency change of 1 GHz every 8–9 min or with a random frequency change every 1–4 min (53–78 GHz band, 0.1–0.2 mW/cm^2). The latter regimen induced an abrupt CAP ‘rearrangement’ in 11 of 12 exposed preparations: the position, magnitude and polarity of the CAP peaks (the initial CAP was polyphasic) drastically changed in an unforeseeable manner. The other exposure regimen altered the CAP peaks components in 30–40 min”

Akoev et al. [59] found EHS-like effects following low intensity MM-wave exposures on the activity of electroreceptors of skates (the article cited here is an English language study, published in an international journal that appears to be similar or identical to the Russian language article cited in ref. [17]). “When a power intensity of 1–5 mW/cm^2 was used at a distance of 1–20 mm from the duct opening only excitatory responses were observed in receptors with electrical thresholds of 4–20 nA”, p. 15 in ref. [59]. Reference [59] states further (p. 17) “It is of interest that at low EMR intensity, the electroreceptors (have) prolonged excitatory responses which differ from responses to the d.c. electrical stimuli (where) the ampullae of Lorenzini completely adapt within a few minutes. Thus it is the long-lasting slow adapting excitatory response that may reflect the peculiarity of the low-intensity millimeter-wave EMR effect on biological tissues.” These results show that low intensity MM-wave EMFs produce long-term hypersensitivity of the electroreceptors. There are similar electroreceptors in sharks, skates and rays and given that the target producing hypersensitivity here is that receptor, it is important to identify the identity of electroreceptor. Bellono et al. [60] showed that the electroreceptor is the VGCC Ca(V)1.3. Other studies implicate excessive [Ca2+]i in electroreception and VGCC activation was also implicated in the Zhang et al. [61] study of the skate electrosensor. We have, therefore, VGCCs implicated as the direct EMF target involved in producing EHS-like responses.

Is there other evidence implicated excessive VGCC sensitivity in producing EHS? One such study was published by Dr. Cornelia Waldmann-Selsam [62]. She studied an EHS patient who showed high sensitivity to extremely low intensity EMFs and who also had a profound parathyroid deficiency. This patient showed very large rapid drops in extracellular Ca^{2+} concentration, including in the blood plasma, following extremely low intensity EMF exposure. Because the only possible mechanism that can produce such a large rapid drop in extracellular Ca^{2+} concentration is a large influx of Ca^{2+} ions into cells of our bodies, this argues strongly for EHS producing large increases in activity of one or more calcium channels in the plasma membranes of cells. Because VGCC activation is known to be the major mechanism of EMFs, all of these findings argue that the VGCCs in EHS become hypersensitive to EMF activation.

The parathyroid deficiency of this patient [62] is of great importance because in people with normal parathyroid function, large drops in extracellular calcium levels produce a rapid increase in parathyroid hormone secretion, which mobilizes calcium from the bones to help restore normal extracellular calcium levels, thus making drops of extracellular Ca^{2+} concentrations in exposed EHS patients with normal parathyroid function more difficult to document. However, these considerations suggest a simple clinical test for EHS patients. Such patients should have large increases in parathyroid hormone following low intensity EMF exposures to which they report sensitivity, whereas normal people should not show such large increases to the same exposures. Because parathyroid hormone can be measured by clinical testing laboratories, this prediction can be easily tested and possibly used as a simple, inexpensive test of EHS.

A fourth MM-wave animal study, discussed above in this section, also suggests possible EHS-like effects in animals. This is the Potekhina et al. [54] study in the rat which found that non-pulsed MM-wave exposures for 3 h or more started to produce apparent sudden cardiac death in these exposed rats. These findings suggest cumulative effects of EMF exposure. However, their relevance to EHS must be viewed as more questionable than are the three studies discussed more immediately above, because there were no measurements which demonstrated that exposures produced increased sensitivity following MM-wave exposures in Potekhina et al. [54].

Three human studies, cited in ref. [17] each showed apparent EHS effects following low intensity non-pulsed MM-wave exposures, including neurological/neuropsychiatric sensitivities [21, 63, 64]. The sensitivities shown in each are brain-related neurological/neuropsychiatric sensitivities that are commonly reported in EHS.

EHS causation by EMF exposures is not only documented by the studies cited above. They are also documented by the largest occupational exposures ever performed, as shown in the Hecht review of such exposures [65]. Reference [65] also documents EMF causation of neurological/neuropsychiatric effects and cardiac effects.

In addition the much earlier US Government (NASA) document [66] also documents EMF occupational exposure causation of neurological/neuropsychiatric effect and cardiac effects [28] lists 15 different published reviews each of which provide substantial bodies of evidence that neurological/neuropsychiatric effects are caused by low-intensity, non-thermal EMF exposures. Lamech [67] showed that smart meter radiation exposure was associated with large increases in EHS, neurological/neuropsychiatric effects and cardiac effects and similar findings were reported in the Conrad study of smart meter radiation.

Four reviews on EHS each report that among the most common sensitivities in EHS patients are neurological/neuropsychiatric sensitivity and cardiac sensitivity [65, 68–70].

It follows from the findings discussed in this section, that EMFs with substantial impacts on our bodies will produce many cases of EHS with the consequent sensitivity responses often including neurological/neuropsychiatric effects and cardiac effects. The next question to be considered here is whether 5G radiation is likely to be among the EMFs that may produce substantial impacts.

Earlier in this paper we discussed two important findings that are important for assessing the probable impacts of 5G radiation. 5G radiation, however, uses extraordinarily high levels of modulating pulses in order to carry extraordinarily high amounts of information per second [36]. Reference [28] cited 10 different reviews each showing that EMFs with modulating pulses produce, in most cases, much higher levels of biological effects than do non-pulsed (continuous wave) EMFs of the same average intensity. If follows that 5G may be predicted to produce very damaging highly penetrating effects because of its extraordinary level of modulating pulsations.

Is there any evidence that 5G radiation produces high human impacts including EHS, neurological/neuropsychiatric effects and cardiac effects?

There has been no biological safety testing of highly pulsed 5G radiation despite calls from many scientists for such testing before any 5G rollout should occur. There have also been no scientific studies of 5G radiation effects after any 5G rollouts, to my knowledge. Consequently, the only evidence we have is from reports of 5G effects in the media. These reports are not, of course, scientific studies but rather are derived from what may be viewed as questionable observations. Nevertheless, due to the lack of any other 5G information, it is important to look at what little information we do have.

Reference [71] is a German news article about protests of German physicians in Stuttgart Germany following a 5G rollout. The physicians report seeing substantial apparent effects on their patients including neurological/neuropsychiatric effects, cardiac effects and EHS. These observations can be seen to be similar to the predicted 5G effects in the previous section. German physicians may be more aware of EHS than are physicians in other countries because the European environmental medicine organization, EUROPAEM, has been headquartered in Germany for many years – [69] is a EUROPAEM-related paper.

There are also reports of neurological/neuropsychiatric effects, cardiac effects and possibly also EHS in Switzerland following 5G rollout in parts of that country [72–74]. These reports may be somewhat less reliable than those from Stuttgart because they come from lay people.

There was much concern about three suicides over an 11 day period of emergency medical technicians working in the first 5G ambulance [75]. This occurred in Coventry, UK. The idea was that 5G could be used to transmit much medical information from the hospital to the ambulance and could also be used to transmit much electronic patient information from the ambulance to the hospital. The first EMT suicide occurred approximately two weeks after the EMTs started working in the 5G ambulance. Among the more common neuropsychiatric effects produced in humans by EMF exposures are depression and anxiety [27], both of which when severe can cause suicide. It is possible that EHS may play a role in the approximate two week time period between the beginning of service of the 5G ambulance and the first suicide. Development of progressively more severe EHS over that two week period may be predicted to produce progressively more severe depression and anxiety.

Again, these are not scientific studies but given the lack of any contrary information, they need to be taken seriously and should be the subject of serious scientific study rather than massive rollout of untested and possibly very dangerous 5G systems. One thing that should be pointed out is that any initial effects on rollout of 5G, are likely to be dwarfed by effects of any full-fledged 5G system communicating with billions of devices on the ‘internet of things." Of course, the effects of such massive amounts of pulsed EMF communication may be further amplified through the action of EHS in the victims.

Search strategies

Articles on important physical or biological properties of coherent electronically generated EMFs were found using two search strategies: The EMF Portal database was searched using coherent or coherence. The Web of Science database and Google Scholar were each searched using electromagnetic fields and coherent.

Reviews on biological including human effects of millimeter waves were searched for in the EMF Portal database searching with the words millimeter waves and limiting responses to review articles. Similarly, reviews were searched in the EMF Portal database using EHS to identify EHS reviews.

The work on EMFs acting primarily via the voltage sensor to activate VGCCs is limited to my own work where only highly cited peer-reviewed articles were cited.

Two specific questions were answered as follows

When it was shown that millimeter wave exposures produced increased sensitivity of the skate electroreceptor, it was important to determine whether the electroreceptor is a VGCC, the most important direct target of EMFs. A Web of Science search using electroreceptor and voltage calcium channel found two studies each showing that the electroreceptor is a VGCC.

It was shown that millimeter waves act directly on the pacemaker cells of the sinoatrial node of the heart to change the beat frequency. It was important to determine whether microwave frequency radiation also target such cells in the sinoatrial node. A search of the EMF Portal database limited to radiation over 1 MHz for studies on sinoatrial node found a study showing that repeated or prolonged exposures produced heart failure-like changes in the sinoatrial node of the rat heart.

Two of the Russian language articles are available as CIA English translations, as shown in the citation list. All other foreign language documents cited where suitable PDFs of the original documents were available were translated into English using Google Translate.

Research funding: The author states that there was no funding involved.

Author contributions: The author has accepted responsibility for the entire content of this manuscript.

Competing interests: The author states that there is no conflict of interest.

Informed consent: Informed consent is not applicable.

Ethical approval: There are no new human or animal studies requiring ethical approval. All reviewed research involving human or animal studies complied with relevant national ethical standards and the Helsinki declaration.

Radio-Frequency Electromagnetic Field Exposure of Western Honey Bees

Arno Thielens[1,2*], Mark K. Greco[3], Leen Verloock[1], Luc Martens[1] & Wout Joseph[1]

Radio-frequency electromagnetic fields (RF-EMFs) can be absorbed in all living organisms, including Western Honey Bees (*Apis Mellifera*). This is an ecologically and economically important global insect species that is continuously exposed to environmental RF-EMFs. This exposure is studied numerically and experimentally in this manuscript. To this aim, numerical simulations using honey bee models, obtained using micro-CT scanning, were implemented to determine RF absorbed power as a function of frequency in the 0.6 to 120 GHz range. Five different models of honey bees were obtained and simulated: two workers, a drone, a larva, and a queen. The simulations were combined with *in-situ* measurements of environmental RF-EMF exposure near beehives in Belgium in order to estimate realistic exposure and absorbed power values for honey bees. Our analysis shows that a relatively small shift of 10% of environmental incident power density from frequencies below 3 GHz to higher frequencies will lead to a relative increase in absorbed power of a factor higher than 3.

Wireless communication is a widespread and growing technology. Most of the wireless networks and personal devices operate using Radio-Frequency (RF) electromagnetic fi lds (EMFs). The current networks rely on frequencies between 0.1 GHz and 6 GHz[1]. These EMFs can be absorbed in dielectric media and can cause dielectric heating[2]. Th s dielectric heating can occur in any living organism, including insects.

Absorption of RF EMFs in insects has been studied previously. Wang *et al.*[3] studied absorption of RF EMFs in mashed codling moth larvae at 27 MHz and 915 MHz. Shrestha *et al.*[4] studied dielectric heating of Cryptolestes ferrungineus S. in different stages (eggs, larvae, pupae, and adults) at 27 MHz. Shayesteh *et al.*[5] exposed Tribolium confusum and Plodia interpunctella to RF EMFs at 2450 MHz[6–8]. are reviews of RF heating of insects. Dielectric porperties of insects are measured by Nelson *et al.*[9] from 0.2 to 20 GHz through the determination of loss of RF EMF power in insect samples (rice weevil, red fl ur beetle, saw-toothed grain beetle, and lesser grain borer). Absorption of RF EMFs was studied by Halverson *et al.*[10] in insects between 10–50 GHz. Thi lens *et al.*[11] used numerical simulations to study absorption of RF EMFs from 2–120 GHz in four insect models. The main conclusions from the aforementioned studies are that (i) RF EMFs can be absorbed and can cause dielectric heating in insects and (ii) this absorption of RF-EMFs is frequency dependent. Th s frequency dependency is important since 5th generation (5 G) networks are expected to partially operate at higher frequencies (up to 300 GHz)[12,13]. Th s shift might induce a change in RF EMF absorption for insects[11].

Western Honey Bees (*Apis Mellifera*) are particularly important insects because of the environmental and economical importance of this species. Therefore, previous studies have focused on the potential effects of EMF exposure of Western Honey Bees. Low-frequency EM properties and exposure of honeybees was studied in[14]. The influence of Low-frequency magnetic fi lds on honey bee orientation has been studied in[15]. There have also been some studies on effects of RF EMF on honey bees. Potential effects of RF EMF exposure on reproduction of honey bee queens were investigated in[16]. Behavioral effects potentially caused by exposure to RF EMFs in honey bees have been investigated in[17–19]. A disadvantage is that these studies are lacking a quantifi ation of the amount of power that is absorbed in the studied honey bees, so called RF dosimetry[20]. On the other hand, this absorption has been determined for a single honey bee worker in[11]. However, Thi lens *et al.*[11] do not provide any coupling of this absorption to a real RF-EMF exposure situation and only study a single honey bee, which provides no

information on the evolution of such absorption as a honey bee goes through different developmental stages. Nor is it clear whether this RF absorption is realistic for other castes, such as drones or queens, in a bee colony.

Therefore, the aims of this study were to numerically evaluate RF-EMF absorption in western honey bees and validate the frequency dependency of this absorption during various developmental stages and experimentally quantify real-life exposure of bees. To this aim, numerical simulations were executed to determine the absorption of RF-EMFs in five different honey bee models: a larva, a queen, two workers, and one drone, obtained using micro-CT imaging. These simulations were implemented as a function of frequency in a broad band, 0.6 GHz up to 120 GHz, that can be used to model both current and future telecommunication frequencies. In parallel, RF-EMF exposure measurements were executed near five bee hives in Belgium, in order to quantify the real exposure of such honey bees. Finally, these measured values were used to rescale the numerical simulations in order to quantify real honey bee absorption and assess a potential change in absorption in case a shift in operation frequencies in future telecommunication networks would occur.

Methods

Studied honey bees, imaging technique, and model development. Images of the studied insects are shown in Fig. 1. All studied insects are western honey bees (*Apis mellifera*), which is the most commonly used honey bee worldwide. Honey bees within a colony are subdivided into different castes. An active viable honeybee colony contains only one queen bee who spends most of her time laying 2,000 to 3,000 eggs per day. The queen is the only reproductive female within the colony and her health is vitally important to the survival of her colony. Damage to her ovaries has the potential to effect the function and survival of her progeny. A queen typically lives between approximately three and five years. From early spring time to mid-summer the queen lays unfertilized "haploid" eggs which develop into drone bees. All drones are males. Their specific role is to mate with a virgin queen so that she can initiate the propagation of a new colony. During this mating season, there are approximately 3,000 to 5,000 drones within any given colony. Drones typically live between one to two months.

A healthy honey bee colony can contain approximately 50,000 individuals. Most of these are sterile, female, worker bees. Worker bees perform all the tasks within a colony to keep it full of provisions and free from disease. Th s involves feeding and nursing larvae, foraging for nectar and pollen, storing nectar and pollen, guarding the entrance, tending to the hygiene of the queen-workers-drones and maintaining a clean hive environment. Workers live for three to four weeks during the active seasons (spring-summer-autumn) and approximately three months during the colder inactive season (winter). There are approximately 3,000 (winter) to 10,000 (summer) larvae present at any given time.

We chose representatives from all three castes within a honeybee colony, one queen bee, two worker bees, one drone bee and one worker larva. All honey bees were scanned at the Western Sydney University National Imaging Facility (Sydney, Australia) using a bench-top MicroCT scanner (Quantum GX MicroCT Imaging System, PerkinElmer, Hopkinton, MA, USA). The parameters used during this scanning depended on the scanned bee. Such scans are made using different projections, at different time intervals on the scanners settings.

The rotation between projections also depends on the scanner's settings and the studied honey bee (see below for full description).

Worker 1. The insect named 'Worker 1' is the same bee studied in[11], which had a full body length of approximately 11.0 mm long, is 5.0 mm wide, and had a mass of approximately 900 mg. During the scanning of Worker 1, the Micro-CT scanner was operated using the following parameters: 50 kVp, 80 mA, and a 2048 $\times$ 2048 pixels image matrix. This resulted in scans with a 20 μm isotropic voxel size. Each projection had a scanning time of 3.0 s, with 3.0 s rotation time in between projections. The total scan time for Worker 1 was approximately 18 min.

Worker 2. The second honey bee worker (Worker 2) has a full body length of 13 mm with cross sectional dimensions of 6.8 mm and 5.4 mm and a mass of approximately 900 mg. For Worker 2, the scanner was operated using the following parameters: 40 kVp, 70 mA, and a 2048 $\times$ 2048 pixels image matrix. The isotropic voxel size was 100 μm. Each projection had a scanning time of 1.5 s. There was a 3.0 s rotation time in between each projection. The total scan time for the whole bee was approximately 10 min.

Larva. Larvae of this age (three weeks) are typically approximately 16 mm long with an approximate mass of 900 mg. The scanned larva was curled up, which made estimating its full body dimensions difficult, but the sample fitted within a $14 \times 7 \times 15$ mm^3 box. Th s scanning of the larva was done using the following parameters: 50 kVp, 80 mA, and a 2048 $\times$ 2048 pixels image matrix. Th s resulted in scans with a 20 μm isotropic voxel size. Each projection had a scanning time of 3.0 s. and with a 3.0 s rotation time this resulted in a total scan time for the larva of 18 min.

Male drone. The drone has a full body length of 18 mm with cross sectional dimensions of 7.2 mm and 9.4 mm and an approximate mass of 1 g. During the scanning of the drone, the Micro-CT scanner was operated using the following parameters: 40 kVp, 70 mA, and a 2048 $\times$ 2048 pixels image matrix. The isotropic voxel size was 100 μm. Each projection had a scanning time of 1.5 s. The full scan took 180 projections and there was a 3.0 s rotation time in between each projection. The total scan time for the whole bee was approximately 10 min.

Queen bee. The QB has a full body length of 19 mm and cross sectional dimensions of 7.5 times 7.1 mm^2 and an approximate mass of 1100 mg. The queen was scanned was using the following parameters: 40 kVp, 70 mA, and a 2048 $\times$ 2048 pixels image matrix. The isotropic voxel size was 250 μm. Each projection had a scanning time of 1.5 s. There was a 1.5 s rotation time in between each projection. The total scan time for the queen bee was approximately 10 min.

Development of 3D models. The software running on the Quantum GX, bench-top MicroCT scanner was used for all honey bees to reconstruct the 180 projection images. Those were then converted into a 2D rendered image stack of 512, 16 bit bitmap images. Finally, the BeeView volume rendering software (DISECT Systems Ltd, Suffolk, UK) was used to acquire Bee volume data from the image stack. All 3D models of the insects were created using the software TomoMask (www.tomomask.com). We used the same approach as in[11]. The image stack for each honey bee was imported into TomoMask, which also required the pixel and slice spacing. The software generated a 3D model using a marching cubes algorithm[21]. Th s model was then exported as an STL (STereo Lithography)[22] file. Th s is a commonly used format to describe surface geometry. The models were also smoothed using the Taubin λ/μ smoothing scheme[23] implemented in MeshLab[24]. The dimensions of the models and mesh integrity were checked (and corrected if necessary) before simulations using Netfabb (Autodesk, San Rafael, CA, USA).

Numerical simulations and RF EMF exposure conditions. Electromagnetic, numerical simulations were executed to estimate electromagnetic fi lds in and around the honey bees under far-field exposure. Far-field exposure is in this manuscript defi ed as RF-EMF sources being more than $2D^2/\lambda$ away from the insects, with D the largest dimension of the RF source and λ the wavelength of the RF-EMFs. Th s is often referred to as the Fraunhofer far-fi ld limit[25]. In general, far-fi ld RF-EMF sources can be located in any direction from the honey bees. Therefore, different approaches exist to model such far-fi ld exposure to RF-EMFs: a stochastic method where far-fi ld exposure is decomposed in sets of plane waves according to certain statistics is used in[26,27], while a more limited set of plane-wave exposures coming from six predefi ed directions along the main axis of the exposed subject or animal are considered in[11,28]. In this study, we have chosen to work with the latter method. We have modeled exposure of the studied honey bees by a set of 12 incident plane waves traveling along six directions defined by a Cartesian coordinate system, see Fig. 2. For each direction, two orthogonal incident electric field polarizations were chosen, since any other free-space E-fi ld polarization can be obtained using a linear combination of both. All incident plane waves have a root-mean squared electric fi ld strength of 1 V/m. Th s value is chosen to facilitate renormalization to any potential value of incident fi ld strenght.

Numerical simulations were executed using the Finite-Difference Time-Domain (FDTD) method implemented in Sim4life (ZMT, Zurich, Switzerland). Th s is a common technique used to determine RF-EMF in and near homogeneous and heterogeneous dielectric objects[11,26,28], such as the honey bees studied in this paper. In this method, the simulation domain is divided in cubes using a three-dimensional rectilinear grid. Depending on the wavelength, feature sizes of the objects in the simulations, and the desired spatial accuracy, a different spatial step is used to discretize the simulation. The FDTD algorithm requires a grid step smaller than one tenth of the smallest wavelength in the simulation domain in order to return stable solutions[29]. Since this is a time-domain technique, it requires a predefi ed simulation time in order to reach a steady-state solution, which will again depend on the chosen spatial resolution, the wavelength, and the size of the simulation domain.

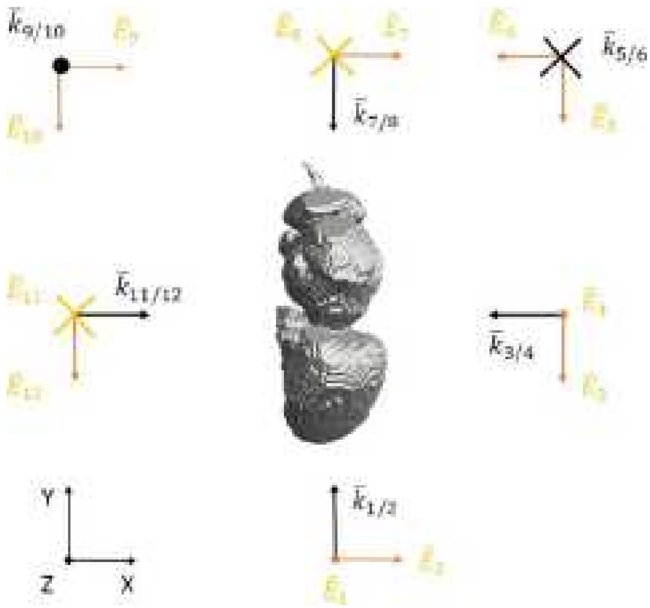

Figure 2. Configur tion of the RF-EMF plane-wave simulations. Twelve potential RF plane waves incident from six directions are incident on the insect (honey bee drone shown here in grey, top view). Orange arrows indicate the electric fi ld $\overline{E}_i$ polarizations, while the black arrows indicate the direction of propagation with wave vector $\overline{k}_{i/j}$ of the plane waves. *i* and *j* indicate the simulations' configur tion number, from 1 to 12.

Table 1. Simulations Settings and Dielectric Properties of the Honey Bees.

We executed numerical simulations at nine harmonic frequencies from 0.6–120 GHz (sinusoidal waves at a single frequency). The lower and upper frequency limits were chosen because they correspond to the current limits in terms of simulation size and length that can realistically be supported by our simulation hardware. The simulated frequencies are listed in Table 1 alongside the chosen grid steps in the simulation domain and the number of periods used for every simulation. These settings were the same for each of the five studied honey bee models. The studied insects have certain dielectric properties, quantifi d using the relative permittivity (ε_r) and conductivity (σ). We did not measure the dielectric properties of the studied insects. Instead, we assigned dielectric parameters obtained from[11]. The value at 1 GHz is obtained using the same literature database and interpolation presented in[11]. Table 1 lists these properties. All insects were modeled as homogeneous objects. These configur tions resulted in 12 (plane waves) × 9 (frequencies) × 5 (honey bees) = 540 simulation results.

After each simulation, the internal electric fi ld in the insect model was extracted and used to calculate the total absorbed RF-EMF power (P_{abs}) in the honey bee. P_{abs} is calculated as the integrated product of the conductivity and the squared internal electric fi ld strenght ($\overline{E}_{int}$) over the total volume (V) of the insect:

$$P_{abs} = \int_V \sigma \times |\overline{E}_{int}|^2 .\, dV \tag{1}$$

We report P_{abs} rather than specific absorption rate (SAR) values since we did not measure the mass and density of all the simulated honey bees. P_{abs} is an important quantity since dielectric heating of an insect is proportional to absorbed RF-EMF power[2].

In order to validate our simulations we tested the influence of four simulation settings on the RF-EMF P_{abs}: grid step size, dielectric parameters, angle of incidence, and number of simulated periods. The influence of the grid step is expected to be the most signifi ant at the highest simulated frequency (120 GHz), since the chosen maximal grid step of 0.05 mm is closest to the smallest wavelength in the simulation domain at that frequency in the tissue ($0.05\,mm = 0.045\,\lambda$). Therefore the maximal grid step was set to 25 μm for exposure configur tion number 2 in Fig. 2 for both the Larva and Worker 2 phantoms. In[11], it was demonstrated that the maximal uncertainty on the dielectric parameters occurs between 2 and 3 GHz, with maximal relative deviations of 40%. In order to test the dependency of our simulation results on the chosen dielectric parameters, we executed four additional FDTD simulations in exposure configur tion number 2 shown in Fig. 2 using the Worker 2 phantom. In these simulations the dielectric parameters (ε,σ) were changed to: (1.5.ε, 1.5.σ), (0.5.ε, 1.5.σ), (1.5.ε, 0.5.σ), and (0.5.ε, 0.5.σ), respectively, allowing for a potential 50% deviation on the dielectric parameters, which should be larger than the uncertainty on the chosen dielectric parameters. We chose to model RF-EMF exposure of the studied honey bees using plane waves incident from 6 directions. However, it is uncertain whether this set of plane waves provides a complete overview of the full range in P_{abs} as function of the angle of incidence. In order to validate our exposure set up, we have executed 20 additional FDTD simulations at 6 GHz using the Worker 2 phantom, where the elevation, azimuth, and polarization angles were generated according to uniform distributions between $[0, \pi]$, $[0, 2\pi]$, and $[0, 2\pi]$, respectively. The settings of these FDTD simulations were the same as those shown in Table 1. Finally, the number of simulated periods was tested at 120 GHz for the Worker 2 phantom in exposure configur tion number 2 shown in Fig. 2 by increasing the number of simulated periods to 120 instead of 30, see Table 1. After each of these validation simulations, the P_{abs} was extracted and compared to the one obtained in the original simulation set.

RF-EMF field measurements. In order to quantify current RF-EMF exposure of honey bees in real exposure scenarios, we executed RF-EMF exposure measurements at five sets of bee hives in Belgium at: Aalter, Merelbeke, Eeklo, Zomergem, and Drongen, see Fig. 3(a). At each measurement site, three different measurements were executed in order to quantify RF-EMF exposure.

First, a spectrum analyzer of the type FSL6 (R&S Belgium, Excelsiorlaan 31 1930 Zaventem Belgium) connected to a triaxial isotropic antenna was used to perform a broad-band RF overview measurement from 80 MHz to 6 GHz. These measurements were executed in two steps: fi st spectral overview measurements were executed from 0.08–3 GHz using a tri-axial antenna TS-EMF (Rhode and Schwartz, dynamic range of 1 mV/m–100 V/m for the frequency range of 80 MHz–3 GHz), followed by measurements from 3–6 GHz using a Clampco AT6000 antenna. At one out of five measurement sites, Drongen, a conical dipole antenna PCD 8250 (Seibersdorf Laboratories, Seibersdorf, Austria) was used for the 80 MHz - 3 GHz measurements. Th s antenna was rotated to obtain three orthogonal polarizations of the electric fi ld. During these overview measurements, the spectrum analyzer measured in maximum-hold modus during 17 and 9 minutes in the lower and higher frequency bands, respectively. The antennas were supported by a plastic tripod and were placed at 1 m in front of the bee hive at a height of 1.5 m from the ground level. Figure 3 shows the studied bee hives and the measurement set up in the field. The 1.5 m height is a typical height at which such EM field measurements[30]. Additionally, this height is mentioned in the ECC(02)04 standard[31]. The purpose of these measurements was to get an overview of which frequency bands were in use at the respective sites. These frequency bands were then investigated further in the second measurements.

Second, the same spectrum analyzer was connected to the tri-axial antenna TS-EMF which was again supported by the same tripod at a height of 1.5 m. The tripod was placed at two distances of 1 and 2 m from the central bee hive. The spectrum analyzer performed root-mean square electric fi ld strength (E_{RMS}) measurements over a measurement period of 6 minutes[2] in each of the telecommunication frequency bands identifi d using the fi st measurement. Each of the three electric field components (E_x, E_y, E_z) were measured individually. E_{RMS} was then obtained as the square root of the sum of squares of the individual components.

$$E_{RMS} = \sqrt{E_x^2 + E_y^2 + E_z^2} \tag{2}$$

The spectrum analyzer measurements in terms of received power on the antenna were then recalculated using the known antenna factor of the tri-axial antenna to incident root-mean-squared electric fi ld strength. The $E_{RMS,i}$ values in each frequency band (i) were then summed quadratically and the square root of that sum is listed as the total instantaneous electric fi ld strength ($E_{RMS,tot}$).

$$E_{RMS,tot} = \sqrt{\sum_i E_{RMS,i}^2} \tag{3}$$

The measurement procedure and measurement settings for these RF-EMF exposure measurements are presented in[32]. The expanded measurement uncertainty (95% confide ce interval) for electric fi ld strength measurements using this set up is $\pm 3\,dB$[30].Th s measurement setup enables the most accurate assessment of *in situ* exposure from various RF-EMF sources[30].

Third, a broadband exposure measurement was executed using a Narda NBM-550 probe (Narda, Hauppauge,NY, USA) connected to an EF 0691 broad-band probe (Narda, Hauppauge, NY, USA) which has a frequency span from 100 kHz to 6 GHz, thus including so-called intermediate frequencies (IF). These IF fi lds are not considered in our numerical simulations. However, we measured those to provide a complete overview of the exposure to electromagnetic fi ld below 6 GHz. The NMB probe was placed on top of the central bee hive and was left there during both RF measurements. The device measured and registered root-mean-squared electric fi ld strengths with a period of 1 s. From those time series of measurements, we obtained the time average and the maximal value.

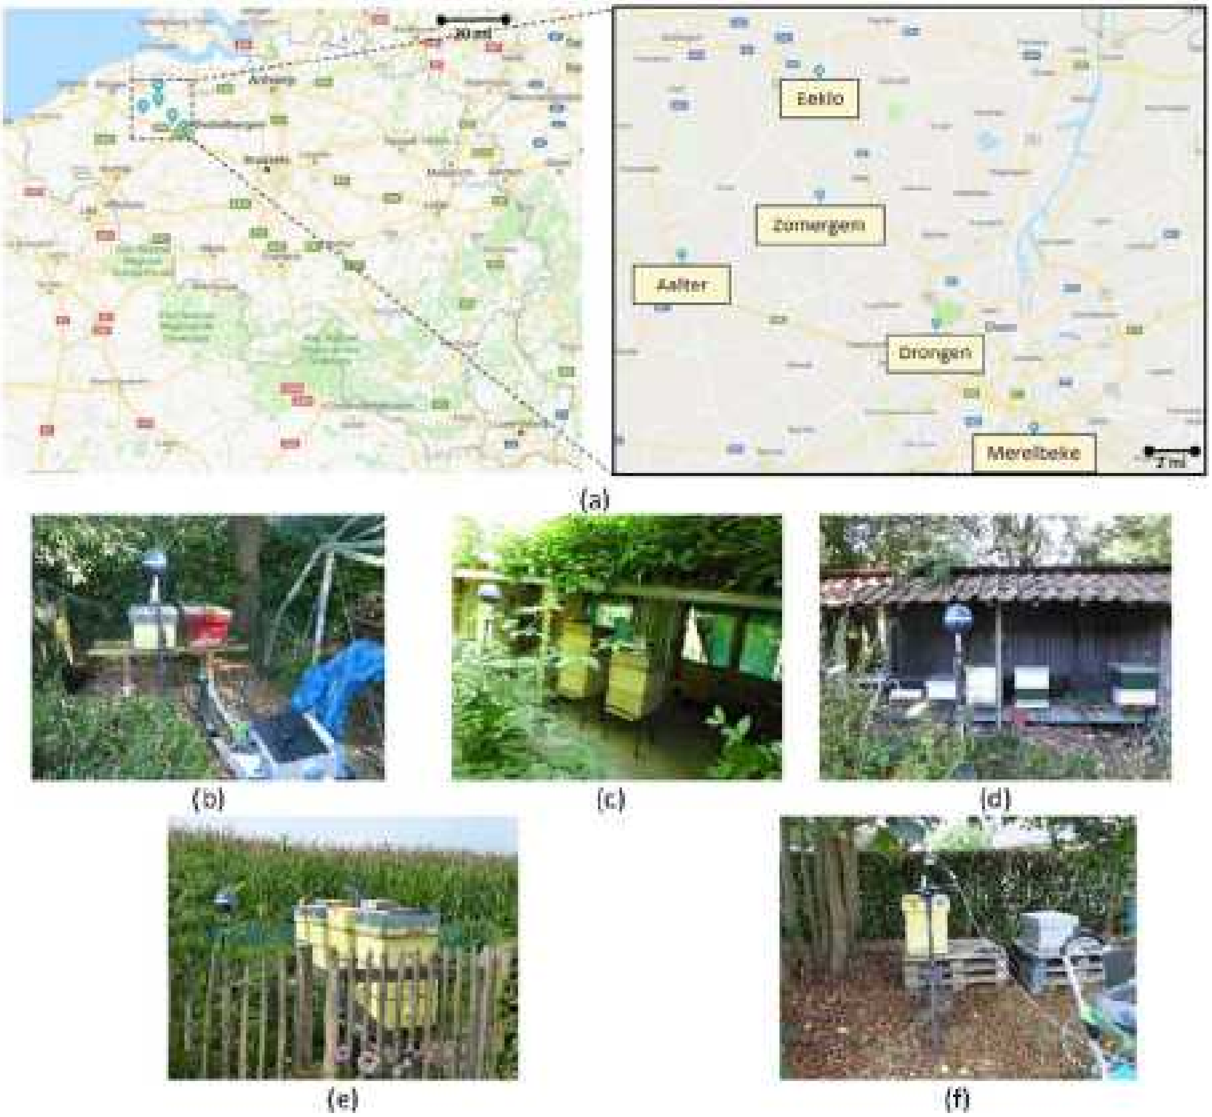

Figure 3. Five measurement locations near bee hives in Belgium: (**a**) Overview of the measrurement locations (source: https://www.google.com/maps, Google Maps, Google, Alphabet inc., Mountain View, CA, USA) Map data: Google, GeoBasis-DE/BKG (**b**) Aalter, (**c**) Merelbeke, (**d**) Eeklo, (**e**) Zomergem, and (**f**) Drongen.

The researchers that executed the RF-EMF fi ld measurements did not use personal devices during the measurements. All wireless devices brought to the measurement site by the researchers were operated in fli ht mode, i.e. any wireless transmissions by those devices were not allowed.

Estimation of realistic RF-EMF absorbed power in honey bees. Realistic P_{abs} absorbed in honey bees can be obtained by rescaling the simulated P_{abs} values using the measured incident fi ld strengths. Therefore, we linearly averaged the total E_{RMS} values measured near the five bee hives at two different positions to obtain an average $E_{RMS,avg}$ value. In order to estimate exposure of honey bees in current wireless networks, we averaged the P_{abs} values using:

$$P_{abs,av}(f < 3\ GHz) = \frac{1}{4}\sum_{i=1}^{4} P_{abs}(f_i) \tag{4}$$

with $f_i = 0.6, 1.2, 2, 3\ GHz$. We only considered P_{abs} values < 3 GHz, since our measurements will show that there are only incident RF-EMFs below 3 GHz in the current environment of honey bees in Belgium. Th s value is then rescaled using:

$$P_{abs,real}(f < 3\ GHz) = \frac{E^2_{RMS,avg}}{1\ V^2/m^2} \times P_{abs,av}(f < 3\ GHz) \tag{5}$$

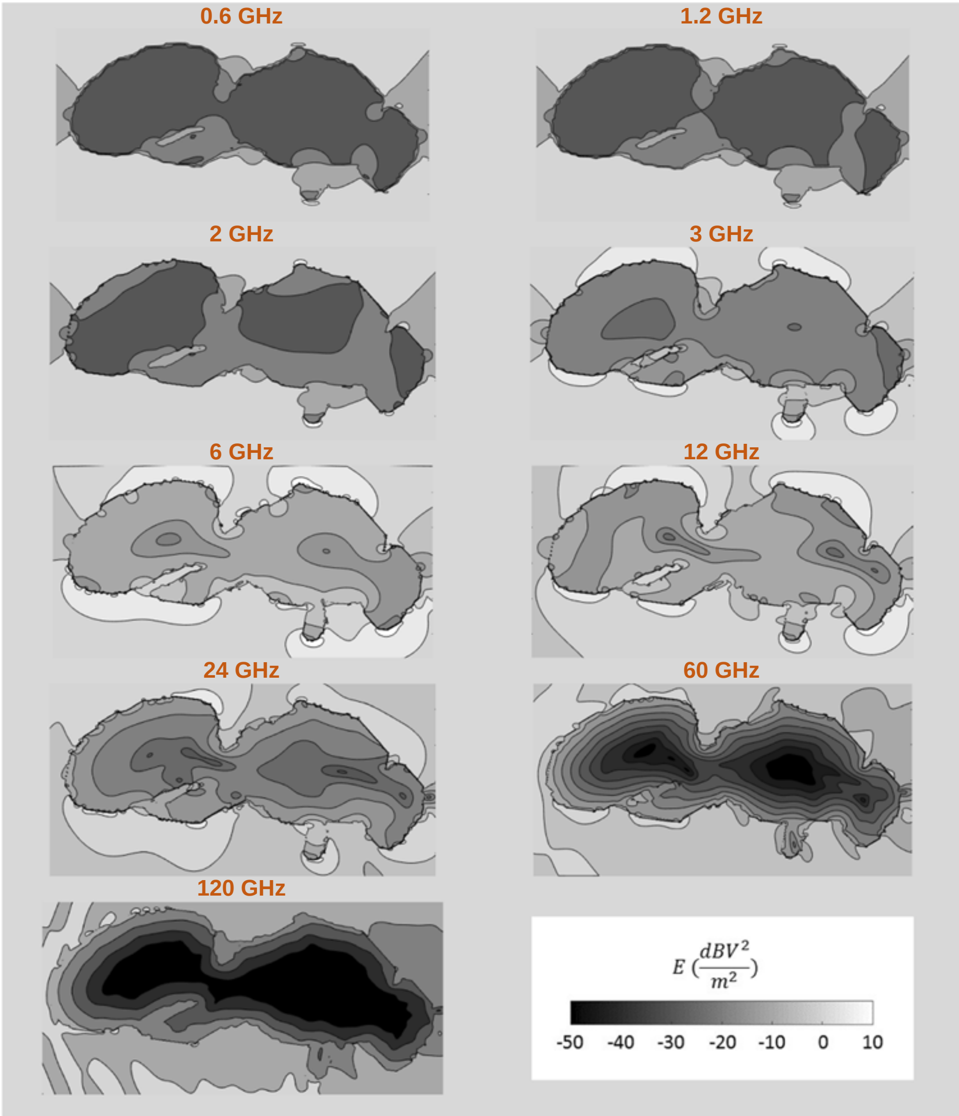

Figure 4. Relative electric fi ld strength in and around a mid-sagittal plane of the Honey Bee Drone at the nine studied frequencies. Grey scale shows the electric fi ld strengths relative to 1 V/m electric fi ld strength.

In order to estimate the effect of a fraction ($p \in [0, 1]$) of the RF-EMF incident fi lds shifting to frequencies higher than 3 GHz we also determine the average P_{abs} for frequencies higher than 3 GHz, using:

$$P_{abs,av}(f > 3\ GHz) = \frac{1}{5}\sum_{j=1}^{5} P_{abs}(f_j) \tag{6}$$

with $f_j = 6, 12, 24, 60, 120\ GHz$. The realistic $P_{abs,real}(p)$ for a fraction p of the power shifted to frequencies higher than 3 GHz is then calculated as:

$$\begin{aligned} P_{abs,real}(p) &= p \times \frac{E^2_{RMS,avg}}{1\ V^2/m^2} \times P_{abs,av}(f > 3\ GHz) + (1 - p) \\ &\times \frac{E^2_{RMS,avg}}{1\ V^2/m^2} \times P_{abs,av}(f < 3\ GHz) \end{aligned} \tag{7}$$

Results

Numerical simulations. Figure 4 shows the relative electric fi ld strength (electric fi ld strength divided by the maximum electric fi ld strength in the simulation domain) in and around the studied drone in a mid-sagittal plane as function of frequency for exposure configur tion number 1 shown in Fig. 2. The internal electric fi lds increase up to 12 GHz and shift towards the outside of the phantom at higher frequencies. At 120 GHz the electric

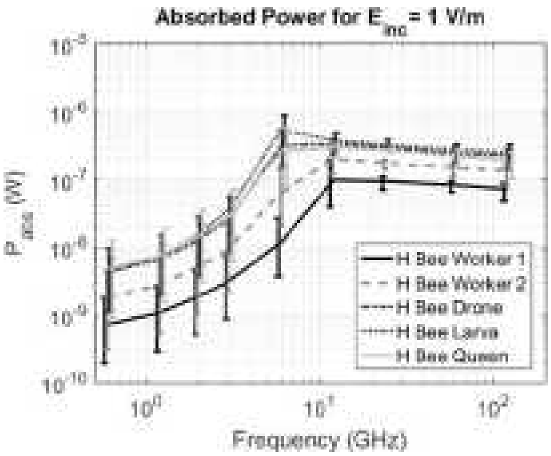

Figure 5. Total absorbed power (P_{abs}) in the five studied honey bees as function of frequency, normalized to an incident plane-wave fi ld strength of 1 V/m at each frequency. The curves indicate the mean values over the twelve plane wave simulations, while the whiskers indicate the maximum and minimum values found at each frequency. The whiskers are slightly off et in order to avoid visual overlap but are all determined at the simulated frequencies described in the Methods Section.

fi ld strengths decreases very rapidly within the phantom and electric fi lds are basically only present in the outer layers of the insect. Th s is caused by a decrease in skin depth that is driven by the increase in conductivity at higher frequencies, see Table 1. Note that the total RF-EMF absorbed power in the insect scales both with the internal electric fi ld strength and the conductivity.

Figure 5 shows the normalized RF-EMF P_{abs} as a function of frequency for the five studied insects from 0.6 GHz up to 120 GHz. The curves connect the linear averages of the 12 P_{abs} values obtained for each honey bee at each simulated frequency, while the whiskers indicate the minimum and maximum P_{abs} values found at those frequencies. All P_{abs} values are normalized to an incident fi ld strength of 1 V/m. Figure 5 shows an increase of P_{abs} over frequency for all studied phantoms up to 6 GHz. When comparing the average P_{abs} at 0.6 GHz and 6 GHz, we found relative increases of factors of 16, 35, 72, 121, and 54 for the Worker Bee 1, Worker Bee 2, Drone, Larva, and queen Bee, respectively. The P_{abs} slightly decreases over frequency beyond 12 GHz for all the studied honey bees. When comparing P_{abs} at 12 GHz and 120 GHz, we found relative decreases of 26%, 34%, 33%, 32%, and 34% for the Worker Bee 1, Worker Bee 2, Drone, Larva, and Queen Bee, respectively. The spread on the P_{abs} values obtained at each individual frequency reduces from up to a factor of 13 below 12 GHz to smaller than a factor 2.5 beyond 12 GHz. Figure 5 shows a general increase of P_{abs} with increasing volume and surface area of the studied insects. Previous studies on whole-body averaged absorbed RF power and specific absorption rate of humans have shown a dependency of these quantities on the absorption cross section, a quantity that scales with volume and/or surface area of an exposed subject. When the diagonals of the smallest rectangular brick that contain the insect phantoms are considered, the honey bee with the smallest diagonal, Worker Bee 1 with a diagonal of 13 mm has the overall lowest average P_{abs}. The Larva, Queen Bee, and Drone all have associated diagonals of 22 mm and have similar average P_{abs} values as function of frequency. The Worker Bee 2 has a diagonal that falls in between Worker 1 and the other insects of 16 mm and also has an average P_{abs} that falls in between the curve for the smaller worker and the other honey bee models, see Fig. 5. We attribute he differences between the two Worker Bee phantoms mainly to the difference in size of both phantoms. The larger Worker Bee 2 phantom has a larger diagonal, surface area, and volume. Th s leads to a higher absorption cross section[33] and higher P_{abs}.

The maximal P_{abs} for the five studied insect models occurs at those wavelengths that are close to the double of this diagonal, which suggests an absorption peak around half a wavelength. The maximum P_{abs} for the Larva model lies in between 3 and 12 GHz, i.e. in between 25 and 100 mm in terms of λ, while the diagonal of said bounding box is 22 mm for the phantom. For the other studied insect models the maximum P_{abs} lies in between 6 and 24 GHz, i.e. in between 23 and 50 mm in terms of λ, with associated phantom diagonals ranging from 16 mm to 22 mm.

As mentioned in the Methods section, the influence of dielectric parameters was studied with simulations using Worker 2 at 2 GHz with altered dielectric parameters. These resulted in P_{abs} values of 6.3×10^{-10} W, 6.3×10^{-9} W, 3.1×10^{-9} W, and 1.8×10^{-9} W, in comparison to 2.0×10^{-9} W for an incident fi ld strength of $1\ V/m$. Th s corresponds to relative deviations of −69%, +210%, +50%, and −10%. These deviations are significant but smaller than the full range of a factor of 5 we observed for the larva at 2 GHz as a function of changing incident angle and polarization. These relative differences are small in comparison to the differences we observe over frequency for the same phantom: a factor of 121 over frequency from 0.6 to 6 GHz.

At 120 GHz we fi d a deviation on P_{abs} smaller than 0.1% when 120 simulation periods are executed in comparison to 30 simulation periods in configuration number 2 shown in Fig. 2 for the Worker 2 phantom. Indicating that the number of simulated periods is sufficient for these simulations. At the same frequency and in the same simulation configur tion, a reduction of the grid step with a factor of 2 resulted in a P_{abs} of 8.6×10^{-8} W and 3.1×10^{-7} W for the Worker 2 and Larva phantoms, respectively, while the regular simulations with 0.1 mm

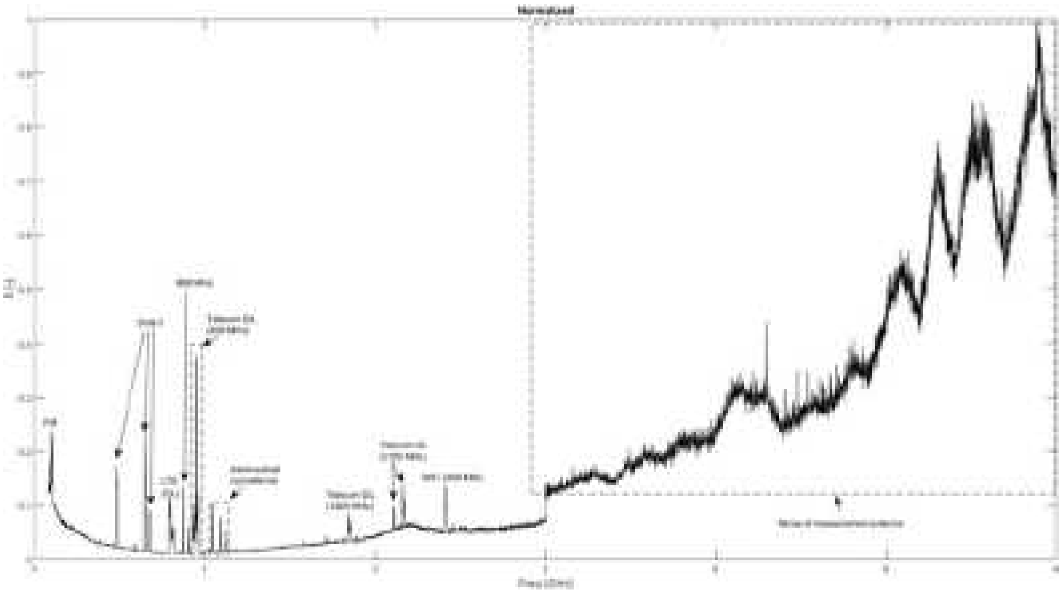

Figure 6. Overview measurement of electric fi ld strength (normalized to maximally measured electric fi ld strength), between 0.8 and 6 GHz, in Aalter. The wireless technologies associated with the different peaks are indicated in the figu e as well.

and 0.05 mm grid steps, respectively, resulted in P_{abs} values of 8.4×10^{-8} W and 3.1×10^{-7} W for an incident fi ld strength of 1 V/m. Th s corresponds to relative deviations of 0.3% and 0.5% for the Worker 2 and the Larva phantoms, respectively, indicating that the chosen grid step was small enough to result in stable numerical results.

The set of 20 incident plane waves with randomized angles of incidence and polarization at 6 GHz using the Worker 2 phantom resulted in an average P_{abs} of $4.5 \times 10^{-8} \pm 1.6 \times 10^{-8}$ W for an incident fi ld strength of 1 V/m, while the set of 12 incident plane waves used to model far-fi ld exposure results in an average P_{abs} of $6.5 \times 10^{-8} \pm 5.3 \times 10^{-8}$ W at the same frequency. The value are fairly close, which indicates that the set of 12 incident plane waves along the main axes is a good proxy for average exposure under a randomized angle of incidence and polarization. The set of twelve plane waves does seem to overestimate exposure at the higher percentiles, since they are signifi antly higher than those obtained using the random set of plane waves.

RF-EMF field measurements. Figure 6 shows an example of an RF-EMF overview measurement at one of the five studied bee hives (Aalter). Figure 6 shows the relative electric fi ld strength, normalized to the maximally measured electric fi ld strength. The different peaks correspond to several individual frequency bands that are used for telecommunication and broadcasting signals. These frequency bands were then measured individually using the same set-up with triaxial antenna and spectrum analyzer at two positions relative to the bee hive on each measurement site using the measurement procedure described in[32].

Table 2 lists the measured E_{RMS} values at the five studied bee hives shown in Fig. 3. As all these measurement sites were rural, private areas, there were no uplink (emissions from a user device to the network) transmissions found. Downlink (DL, this is network to user communication) signals were found at all measurement sites. These signals were generated by three different mobile telecommunications providers in fourteen different frequency bands. The wireless technologies used by the telecommunication operators were: Long Term Evolution (LTE) in frequency bands close to 800 MHz and 1800 MHz, Global System for Mobile telecommunications (GSM) in frequency bands close to 900 MHz, and Universal Mobile Telecommunications Service (UMTS) in frequency bands close to 900 MHz and 2100 MHz. Four other telecommunication bands were identifi d: TETRA (Terrestrial Trunked Radio, 390–395 MHz) which is a technology used by public services (police, fi efi hters, etc.), an Industrial, Scientifi al, and/or Medical (ISM) application around 870 MHz, Digital Enhanced Cordless Telecommunications (DECT) close to 1900 MHz, and Wireless Fidelity (WiFi) at 2400 MHz. Additionally, several frequency bands with RF signals for broadcasting were measured: Frequency Modulated (FM) Radio around 100 MHz, Digital Audio Broadcasting (DAB) around 200 MHz, Digital Video Broadcasting (DVB) at 480–680 MHz. We found one unidentifi d RF wireless transmission at 592 MHz on two measurement sites: Merelbeke and Eeklo. The total E_{RMS} values ranged from 0.016 V/m on both positions in Merelbeke up to 0.226 V/m on position 1 in Drongen. The average E_{RMS} over the ten studied measurement sites was 0.06 V/m. FM Radio was the dominant source of RF exposure on 7/10 measurement positions. In Drongen and in Aalter, GSM 900 DL was the dominant contributor to the RF-EMF exposure. The fi ld strength of WiFi signals depends strongly on the duty cycle used by the wireless technology[34]. The measured E_{RMS} values can be extrapolated to peak values under the assumption of 100% duty cycle. In the case of Aalter, this would result in 0.027 V/m and 0.032 V/m on positions 1 and 2, respectively. In the case of Zomergem, this extrapolation would result in peak E_{RMS} values of 0.059 V/m and 0.016 V/m on positions 1 and 2, respectively. On both measurement sites, a theoretically maximal 90% duty cycle would make WiFi the dominant source of exposure. However, such a network load is unlikely in a rural

area. WiFi was not measured at three out of five measurement sites. Additionally, at all measurement sites, RF EMFs emitted by a pulsed radar or other wireless technologies used in aeronautical surveillance were observed. Th E_{RMS} value of RF EMFs emitted by a radar cannot be accurately measured without having the specifi ations of the radar. Therefore, we can only measure the peak value over the 6 min measurement interval. These fi lds were the highest in Merelbeke, where at position 1 peak E-fi ld values of 0.017 V/m and 2.2 V/m were measured at 1.09 GHz and 1.3 GHz, respectively, while at position 2 peak E-fi ld values of 0.02 V/m and 2.9 V/m were measured at at 1.09 GHz and 1.3 GHz, respectively.

In order to provide the readers with a complete overview of the exposure to EMF fi lds below 6 GHz at the chosen measurement sites, Table 3 lists measured values in the 100 kHz to 6 GHz range using a broadband fi ld

Table 4. Absorbed power in the four studied insects for an incident electric fi ld strength of 0.06 V/m, distributed uniformly over frequencies lower and higher than 3 GHz for different relative fractions.

probe. All the average values are higher than what is obtained from the frequency-selective measurements presented in Table 2, as should be the case since a broader band is considered.

Estimation of realistic RF-EMF absorbed power in honey bees. Using the results presented in Table 2, one can rescale the P_{abs} values shown in Fig. 5 in order to obtain a realistic estimate of the absorbed RF-EMF power in honey bees $P_{abs,real}$. The third to eight columns of the top row of Table 4 list $P_{abs,real}$ assuming that all incident $E_{rms} = 0.06\ V/m$ is uniformly distributed over the simulated P_{abs} values lower than 3 GHz. These values range from 0.1 nW for Worker 1 until 0.7 nW for the Larva and Queen Bee. In each subsequent row, 10% of the incident power density is transferred to frequencies higher than 3 GHz. Th s causes an increase in the estimated $P_{abs,real}(p)$. In order to quantify this increase, the five columns to the right show the relative increase in $P_{abs,real}(p)$ as p increases from 0 to 1. A full shift of all RF-EMF power to frequencies higher than 3 GHz - without changing the incident fi ld strength - would result in relative increases in absorbed power between a factors 24–48 for the studied honey bee models. Even a relatively small shift of 10% of the incident power density to higher frequencies will lead to a relative increase in P_{abs} of a factor higher than 3, see Table 4.

Discussion

Th s study investigates RF-EMF absorption in Western Honey Bees as a function of frequency in the 0.6 to 120 GHz range. To this aim, we used five different models of different honey bees: two workers, a drone, a larva, and a queen. These models were obtained using micro-CT imaging and used for FDTD simulations. These were used to evaluate far-fi ld exposure of honey bees. Th s far-fi ld exposure is modeled as a set of plane waves at harmonic frequencies between 0.6 and 120 GHz. The numerical simulations resulted in P_{abs} as a function of frequency for the different studied honey bees. These simulations were combined with real RF-EMF exposure measurements near bee hives in Belgium in order to estimate realistic exposure values for honey bees.

Micro-CT imaging is a technique that has previously been shown to accurately scan insects[35,36]. The models used in this study have resolutions between 0.02 mm and 0.25 mm, which is larger than the resolution of the micro-CT models using in[11]. Since the smallest grid step used in our simulations is 0.05 mm, the ideal resolution of the insect models would be smaller than that. The larger resolution of the scanning is not a problem for the stability of the FDTD algorithm, but more spatial resolution could be obtained with the same simulation settings. It is expected that the micro-CT models used in this study lead to a better estimation of P_{abs} and the spatial distribution of the electric fi lds than approximate models such as ellipsoids or cylinders[37].

The results of our numerical simulations, see Fig. 5, show an increase of P_{abs} with frequency up to 6–12 GHz. Figure 4 illustrates the mechanism behind this increase: as the frequency increases the EMFs are less likely to diffract around the honey bees, that are relatively small in comparison to the wavelengths $<6\,GHz$, and can penetrate further in the models, generating higher internal electric fi lds and consequently higher P_{abs} values. Figure 4 also shows why the whole-body averaged P_{abs} does not increase beyond 12 GHz. As the conductivity increases, see Table 1, the electric fi lds will decay faster within the honey-bee phantoms, which leads to larger relative volumes within the insect with lower fi lds, see Fig. 4, which will also contribute to the whole-body averaged P_{abs}. Th s effect also causes the P_{abs} to have a smaller dependency (variation) on incident angle and polarization, see Fig. 5. We also observe that both the frequency-dependency of the P_{abs}, i.e. the transition point between sharp increase in P_{abs} over frequency and slight decrease over frequency, and the magnitude of the P_{abs}, i.e. the off et of the P_{abs} curve, depend on the honey bee's size. Th s effect was previously observed in[11]. In general, the results presented in this manuscript are in excellent agreement with those presented in[11]. The results in terms of P_{abs} obtained for the honey bees in this study fall right in between those obtained in[11] for the smaller Australian Stingless Bee and the larger Desert Locust, which confi ms again the dependency of P_{abs} on phantom size. The same size-related effect was described for humans in[28,33,38] and comparable frequency trends were observed in humans that have larger full-body sizes at MHz frequencies[28,38]. It should be noted that this manuscript focused on exposure of individual insects in free space. In reality, honey bees might cluster, creating a larger absorption cross section and potentially higher absorption at lower frequencies.

The FDTD simulations presented in this manuscript use dielectric properties that were obtained from the literature survey executed in[11]. Ideally, these dielectric parameters would be obtained for the honey bees studied in this manuscript. However, as shown in[11], most studies on dielectric properties of insects in literature[3,39–41] show similar frequency dependencies of those dielectric parameters. We have executed additional numerical simulations to test for the uncertainty on the dielectric parameters and found deviations up to 210% on P_{abs}, which is signifi ant but still smaller than the variations that exist due to changing angle of incidence and polarization at a fi ed frequency, or changes in frequency. We modeled the insects as homogeneous dielectric objects, while in reality they have heterogeneous dielectric parameters. Even though the FDTD algorithm will always require an averaging of dielectric parameters over the cube size, further developments in honey bee and insect phantoms should be focused on the inclusion of multiple tissues in order to refi e these models.

In-situ RF-EMF measurements were executed using a measurement set up consisting out of a spectrum analyzer connected to an isotropic, triaxial antenna according to the measurement procedure listed in[32]. We measured total incident E_{RMS} between 0.016 V/m and 0.226 V/m in five rural environments with a linear average of 0.06 V/m and a quadratic average of 0.1 V/m. Joseph *et al.*[32] measured a median total E_{RMS} value of 0.09 V/m over several rural locations in Belgium, the Netherlands, and Sweden. Bhatt *et al.*[1] measured an average E_{RMS} value of $0.07 \pm 0.04\ V/m$ in rural environments in Belgium. Both previous studies of rural RF-EMF exposure are close to what we found in this manuscript and certainly within the measurement uncertainty of 3 dB on our measurements.

As our RF-EMF exposure measurements near bee hives demonstrate, see Table 2, most of the current RF-EMF exposure is located at frequencies $\leq 1\ GHz$. Additionally, Fig. 5 demonstrates that the P_{abs} in all studied Honey bee models is lowest at frequencies $\leq 1\ GHz$. Th s implies that in reality, potential shifts in telecommunication frequencies to higher frequencies might induce even larger increases that the ones estimated in Table 4 since in that analysis an average value over all P_{abs} values $\leq 3\ GHz$ is assumed.

Strengths and limitations. This manuscript presents several contributions to the state of the art in the fi ld of RF-EMF exposure assessment of insects. First, to the best of the authors' knowledge, this is the only paper where a numerical RF dosimetry is presented for different developmental stages of honey bees. Second, this is the only study that combined real, *in-situ* exposure measurements with numerical simulations of RF-EMF exposure of insects in order to estimate a realistic exposure of honey bees. In comparison to our previous study[11], we considered a broader frequency range from 0.6 GHz up to 120 GHz, which is more in line with the frequencies used in the current telecommunication networks (3 G and 4 G). Finally, this study presents a unique quantifi ation of real-life exposure of honey bees and estimations of how this might change if future frequency shifts in that exposure might occur. A disadvantage of this study is that we did not executed dielectric and thermal measurements in order to obtain dielectric and thermal properties of the studied honey bees. We obtained dielectric properties from literature and were able to execute electromagnetic simulations. We did not perform thermal simulations in this study. Another disadvantage is that we modeled far-fi ld exposure by a limited number of plane waves, while previous studies have shown that a large set of plane waves is necessary to properly model far-field exposure[26]. We did executed a validation of our exposure set up by comparing it with a set of random plane wave exposures and found good correspondence, certainly close to the mean/median. Finally, we used FDTD simulations that are faced with uncertainties[29] and used models that have a limited spatial resolution. Th s is a disadvantage of any RF-EMF simulation study in comparison to a study that relies on measurements of real insects.

Future research. Our future research will focus on executing exposure measurements of insects in order to validate the RF-EMF P_{abs} values and the dielectric parameters. Additionally, we would like to execute thermal simulations of honey bees and other insects under RF-EMF exposure. Finally, we aim to work on the development of more insect phantoms, with more spatial accuracy and potentially several independently identifi d tissues.

Conclusions

Exposure of Western Honey Bees (*apis mellifera*) to radio-frequency (RF) electromagnetic fi lds was studied using a combination of *in-situ* exposure measurements near bee hives in Belgium and numerical simulations. The simulations use the fin te-difference time-domain technique to determine the electromagnetic fi lds in and around five honey bee models exposed to plane waves at frequencies from 0.6 GHz up to 120 GHz. These simulations lead to a quantifi ation of the whole-body averaged absorbed radio-frequency power (P_{abs}) as a function of frequency. The average P_{abs} increases by factors 16 to 121, depending on the considered phantom, when the frequency is increased from 0.6 GHz to 6 GHz for a fi ed incident electric fi ld strength. A relatively small decrease in P_{abs} is observed for all studied honey bees between 12 and 120 GHz. RF exposure measurements were executed on ten sites near five different locations with bee hives in Belgium. These measurements resulted in an average total incident RF fi ld strength of 0.06 V/m, which was in excellent agreement with literature. Th s value was used to assess P_{abs} for those honey bees at those measurement sites. A realistic P_{abs} is estimated to be between 0.1 and 0.7 nW for the studied honey bee models. Assuming that 10% of the incident power density would shift to frequencies higher than 3 GHz would lead to an increase of this absorption between 390–570%. Such a shift in frequencies is expected in future networks.

Abstract

Fifth generation networks (5G) will be associated with a partial shift to higher carrier frequencies, including wavelengths of insects. This may lead to higher absorption of radio frequency (RF) electromagnetic fields (EMF) by insects and could cause dielectric heating. The yellow fever mosquito (*Aedes aegypti*), a vector for diseases such as yellow and dengue fever, favors warm climates. Being exposed to higher frequency RF EMFs causing possible dielectric heating, could have an influence on behavior, physiology and morphology, and could be a possible factor for introduction of the species in regions where the yellow fever mosquito normally does not appear. In this study, the influence of far field RF exposure on *A. aegypti* was examined between 2 and 240 GHz. Using Finite Difference Time Domain (FDTD) simulations, the distribution of the electric field in and around the insect and the absorbed RF power were found for six different mosquito models (three male, three female). The 3D models were created from micro-CT scans of real mosquitoes. The dielectric properties used in the simulation were measured from a mixture of homogenized *A. aegypti*. For a given incident RF power, the absorption increases with increasing frequency between 2 and 90 GHz with a maximum between 90 and 240 GHz. The absorption was maximal in the region where the wavelength matches the size of the mosquito. For a same incident field strength, the power absorption by the mosquito is 16 times higher at 60 GHz than at 6 GHz. The higher absorption of RF power by future technologies can result in dielectric heating and potentially influence the biology of this mosquito.

Author summary

Radio Frequency (RF) exposure of the *A. aegypti* mosquito can lead to absorption and dielectric heating. We used Finite Difference Time Domain (FDTD) simulations between 2 and 240 GHz to study the RF power absorbed by the insect and the distribution of the electric field (EF) in and around it. For this, three male and three female mosquito 3D models were constructed from micro-CT scans. We used high resolution models and

dielectric properties, both retrieved from real insects, to gain realistic outputs. For increasing frequency up to 90 GHz, the absorbed power increases for all models. At 90–120 GHz, the wavelength is comparable to the body size, and the increase in absorbed powers reaches a maximum. Therefore, moving to higher frequencies in 5G, implies higher absorbed power and possibly higher dielectric heating of the insect.

Introduction

With the upcoming fifth generation networks (5G) in wireless telecommunications, the Radio Frequency (RF) electromagnetic fields (EMF) used as carriers will partly shift to higher frequencies. Current telecommunication networks make use of frequencies of 0.1–6 GHz [1], while the carrier frequencies for 5G networks can go up to 300 GHz, entering the millimeter-wave frequency range [2]. For these higher frequencies, the wavelength becomes comparable to the body size of insects. When wavelength and body size become of the same order of magnitude, an increase in efficiency of absorption of RF-EMFs in the body is expected [3]. The absorption of RF-EMF in biological tissues can lead to the dielectric heating of an organism [4]. With the alternating electric field and polarity, the movement of free ions and dipoles causes the heating in dielectric material [5]. This RF heating of insects has been repeatedly investigated as a method to kill insects in low-moisture foods, grain, or wheat storage [6–13]. The difference in dielectric properties, RF absorption and consequential dielectric heating between insect and food, is used to heat the insect up to a lethal temperature for the insect, while the food is not damaged. The frequency and field strength are chosen depending on the type of stored food and the infesting insect.

The insect of interest in this paper is the yellow fever mosquito, *Aedes aegypti*, it is known as a vector for diseases such as yellow fever, dengue fever and zika virus infections [14, 15]. According to the Centers of Disease Control and Prevention in the U.S., yellow fever cases and deaths worldwide are estimated at 200,000 and 30,000 each year [16], respectively. The yellow fever mosquito is a tropical species favouring a hot and humid environment. Temperature affects the life cycle and feeding behaviour of the mosquito and the reproduction of the viruses [14, 15]. RF power absorption and dielectric heating can cause disturbance in for example the behaviour or development of the mosquito. Another interesting consequence of dielectric heating and higher body temperature, may be the spread of the mosquito to areas that are normally unfavorable for them. Be that as it may, the focus in this paper is on the RF power absorption, the dielectric heating or other consequences are not considered.

The absorbed RF power in four different insect species has been examined through numerical simulations by Thielens *et al.* using models created from real insects [17, 18] and it was observed that absorbed power was maximal for wavelengths comparable to the insects' body size. However, the simulations in [17, 18] relied on unverified assumptions regarding the dielectric properties of the studied insects and these arthropods were at least a factor 1.5 larger than the yellow fever mosquito in terms of volume.

The effects of RF-EMF exposure can have an important impact on insects, they have been investigated experimentally on several insects. Influences were reported on e.g. the development and mating of honeybees (reduced hatching of honey bee queens) [19], behaviour of ants (the locomotion) [20], and the morphology of mealworm beetles during development (abnormalities of appendages) [21]. The collective position behaviour of mosquitoes *A. aegypti* was examined under relatively low-power RF-EMFs in the frequency range of 0.01–20 GHz, without any conclusive results about the position of the mosquitoes as a reaction to the

RF-EMF exposure [22]. The absorption of RF-EMFs of mosquitoes has however never been investigated, nor their dielectric properties.

The dielectric parameters, relative permittivity (ϵ_r) and conductivity (σ), have been characterized for other insects before. Coaxial-probe measurements were done on stored-grain insects [23], the Colorado Potato Beetle [24], and insects in dried nuts and fruits [6]. An alternative resonance method has been used as well to investigate dielectric properties of different insects [25].

In this paper, the frequency-dependency of the RF power absorption for *A. aegypti* was investigated by means of numerical simulations at frequencies from 2–240 GHz. This frequency range was chosen to cover both the legacy and 5G telecommunications range and to include wavelengths similar to the mosquito dimensions. To this end, a unique set of high resolution 3D models of yellow fever mosquitoes was developed using micro-computed tomography (CT) scanning. The models were combined with accurate dielectric property measurements in adult yellow fever mosquitoes in order to execute finite-difference time-domain (FDTD) simulations, which resulted in EMF distributions in and around the studied insects. These results provided insights in the power absorption in the mosquitoes' body, but also in the distribution of this power absorption over the body and different body parts. The novel aspects of this study are (i) the simulations on *A. aegypti* in far field EMF exposure between 2–240 GHz, (ii) measurements of dielectric properties in *A. aegypti*, (iii) the creation of 3D models based on micro-CT scanning of real mosquitoes, and (iv) assessment of the RF absorption of the full mosquito body and of the different body parts. Our results provide an important input for studies that investigate the spread and biology of *A. aegypti* on the one hand and regulators and telecommunication operators who are re-evaluating the guidelines regarding RF-EMF exposure in their planned telecommunication networks on the other hand.

Materials and methods

The RF power that is absorbed by yellow fever mosquitoes is studied by means of simulations, i.e. solving Maxwell equations numerically. The simulations require a 3D model and dielectric properties of the yellow fever mosquito as inputs. The 3D models were based on scans of real dried yellow fever mosquitoes and the dielectric properties were measured from a mixture of yellow fever mosquitoes.

Mosquitoes

The yellow fever mosquito specimens were taken from the *Ae. aegypti* Rockefeller colony kept in the insectary facility at the Swiss Tropical and Public Health Institute. The mosquitoes were reared at 26–28°C and 60–80% relative humidity with a 12:12 h day:night light cycle. Larvae were fed with ground TetraMin flakes (Tetra GmbH, Melle, Germany) and adults were provided 10% sucrose solution ad libitum. Females were artificially fed with pig blood received from the local abattoir to keep the stock colony, however the specimens used for the measurements in the current study were unfed.

Scanning and modelling method

In the simulations of RF-EMF exposure of mosquitoes, the models of the insects should be as close to reality as possible. Therefore, real mosquitoes were dried and scanned with a micro-CT scanner to form 3D models. The samples were scanned using the custom-designed HECTOR scanner [26] of the Ghent University Center for X-ray Tomography (UGCT; www.ugct.ugent.be) with a tube voltage of 70 kV and a target power of 10 W. During a full 360°rotation, 2400 projection images were acquired at an exposure time of 1 s each. The samples were positioned on floral foam and positioned close to the X-ray source, resulting in a geometrical magnification of approximately 50. The raw data was reconstructed using Octopus Reconstruction at a reconstructed voxel size of $(4.012)^3$ μm^3. To reduce edge enhancement artefacts and increase the signal-to-noise ratio in the data, the Paganin phase retrieval algorithm was applied [27, 28]. To extract the STL model from the 3D volume, each mosquito datastack was loaded into VGStudio MAX (Volume Graphics, Heidelberg, Germany). Areas where the mosquito touched the floral foam were removed manually. After applying a median filter, the region containing the outer structure of the insect was selected using a growing area function. Although many inside features were not selected with this procedure, leaving large unwanted cavities in the model, this was compensated for by selecting these internal regions separately and merging the volumes. Finally, these regions were converted to a single cohesive STL file per mosquito.

Dielectric properties

In order to determine the internal EMFs inside the insect models developed in the previous section, Maxwell's equations can be solved numerically. For this purpose, the dielectric properties, relative permittivity (ϵ_r) and conductivity (σ) of the insect need to be known and inserted into the equations. The novel dielectric assessment kit for thin layers (DAK-TL) from SPEAG (Schmid & Partner Engineering AG, Switzerland), which is based on the open coaxial probe method, was used to perform dielectric spectroscopy [29]. DAK-TL overcomes the long existing limitation associated with Open-Ended Coaxial Probes (OCP) where sufficiently large samples are needed to avoid reflections at the boundaries. Using full-wave analysis of the open coaxial probe geometry, the complex dielectric properties are calculated from sample thickness and the complex reflection coefficient measured with the vector network analyzer (VNA). The DAK-TL-1.2E probe (5–67 GHz) was used in combination with a ZVA67 VNA (Rohde & Schwarz, Munich, Germany) to perform measurements over the aforementioned frequency range. The measurement resolutions are set to 50 MHz and 250 MHz for the interval 5–6 GHz and 6–67 GHz, respectively. The DAK-TL system was calibrated using the standard 3-point calibration prior to each measurement session: open, short (copper strip), and de-ionized water as the load. A force of 800 N was applied during the short calibration to ensure a good contact between the probe and the copper strip. The validity of calibration was verified by measuring another reference liquid, namely 0.05 M saline solution with known dielectric properties. The measurement uncertainty values (Table 1) that includes possible systematic errors due to design, calibration, thickness measurement uncertainties, and VNA noise were established according to [30].

Table 1. Expanded uncertainties (k = 2) in the measurements of dielectric parameters made with the DAK-TL-1.2E Probe.

As poikilotherms, the environmental temperature is an important parameter affecting the life of yellow fever mosquitoes. The dielectric characterization was performed at 22˚C, this temperature was chosen because it is a temperature where flight activity, host-seeking, and blood-feeding are not impaired. [31] A metallic Petri dish (inner diameter = 30 mm, height = 4 mm) was used to characterize the homogenised mosquito sample. The different tissues of the mosquito are small in sample size (approximatly < 1 mm^3), dissecting multiple samples is very time consuming and thus it was chosen to work with a carefully prepared homogenized mixture. A reproducible method for preparing an insect-mixture for the measurements was developed. In this procedure, approximately two thousand A. aegypti mosquitoes, including both males and females, were used for dielectric properties measurements. First, the mosquitoes were euthanized prior to measurements using CO2. Afterwards, the samples were homogenized using a small battery-operated mortar in combination with the application of mechanical force. This resulted in a homogeneous semi-solid mosquito-mixture of about 2 ml, for which aliquots were prepared.

To measure the complex permittivity $\hat{\epsilon}$ of each of the two samples, the Petri dish filled with the mixture was slowly moved towards the probe and stopped when the distance between the Petri dish bottom plate to the probe was 1±0.02 mm. This was repeated three times for both samples by removing the slurry from the holder and refilling the Petri dish. The complex permittivity of each sample was determined as the average over these three measurements. The complex permittivities used in the simulations are the averaged values from the two sample characterizations.

The studied frequency region of interest extends outside the measured range of 5 to 67 GHz. Therefore, the dielectric properties are extrapolated down to 2 GHz (within the 4G frequency range) and up to 240 GHz (in the millimeter-wave mobile broadband [2]). The properties were extrapolated by the Debye-model [32] whose coefficients were determined from a least mean square fit to the measured complex permittivity of the mixture, as in [24]:

$$\hat{\epsilon} = \epsilon' - j\epsilon" = \epsilon' - j\frac{\sigma}{\omega\epsilon_0} = \epsilon_\infty + \frac{\epsilon_s - \epsilon_\infty}{1 + j\omega\tau} + \frac{\sigma_s}{j\omega\epsilon_0} \quad (1)$$

with $\hat{\epsilon}$ the complex relative permittivity of the sample, σ the conductivity of the sample, ω the angular frequency, ϵ_s the static permittivity, ϵ_∞ the permittivity at infinity, τ the relaxation time, ϵ_0 the permittivity of free space and σ_s the static conductivity. The measured data is fitted considering firstly one relaxation time and secondly two relaxation times. In the second case, Eq 1 for the real and imaginary part (loss factor) of the relative permittivity reads as:

$$\epsilon' = \epsilon_\infty + \frac{\Delta\epsilon_1}{1 + j\omega\tau_1} + \frac{\Delta\epsilon_2}{1 + j\omega\tau_2} \quad (2)$$

$$\epsilon" = \frac{\sigma}{\omega\epsilon_0} = \frac{\sigma_s}{\omega\epsilon_0} + \frac{\Delta\epsilon_1\omega\tau_1}{1 + (\omega\tau_1)} + \frac{\Delta\epsilon_2\omega\tau_2}{1 + (\omega\tau_2)} \quad (3)$$

where $\Delta\epsilon_i$ is the difference between the static permittivities ϵ_s, i and the permittivity at infinity ϵ_{inf}, with i = 1, 2 corresponding to the two relaxations.

Numerical simulations

The mosquito models and the measured dielectric properties were used in numerical simulations with the commercial software Sim4Life Version 5.2.1 (ZMT Zürich MedTech AG, Zürich, Switzerland), where the FDTD method was used to determine the internal electric field inside and around the mosquito body. This study investigated exposure in the far-field or

Fraunhofer radiation region. In this zone the following conditions hold for the separation distance between insect and RF-EMF source (r): $r \gg 2l^2/\lambda$ with λ the wavelength and l the largest dimension of the RF source and the insect [33]. In this region, any RF-EMF field can be described as a set of incident plane waves [33]. This technique was previously used to determine the RF-EMF absorption in heterogeneous human body models [3] and for other insects [17, 18]. The dielectric heating is proportional to the the total absorbed RF-EMF power (P_{abs}), which in its turn can be found from the internal electric field:

$$P_{abs} = \int \sigma \times |\vec{E}_{int}|^2 \cdot dV \tag{4}$$

with σ the conductivity, $|\vec{E}_{int}|$ the root mean square internal electric field strength and V the volume of the insect. P_{abs} depends on the frequency, as both σ and E_{int} are dependent on the frequency. Therefore, different frequencies were investigated: 2, 6, 12, 24, 60, 90, 120 and 240 GHz. For a flying or resting mosquito, the polarization and angle of incidence of far-field EMFs is unknown a priori. Therefore, twelve incident plane waves were considered to model the far-field exposure, as shown in Fig 1. This was the same configuration as used in [3]: 6 directions along Cartesian axes with 2 orthogonal polarizations per direction. The insects were aligned with the length of the body along one of the axes. In the simulations, all plane waves had a root mean squared electric field strength of 1 V/m. In real situations, this field strength can vary from 1 V/m, since the absorbed RF power scales quadratically with the incident field strength, it can be calculated for an arbitrary field strength given the value at 1 V/m:

$$P_{abs,real} = P_{abs}(1V/m) \cdot \frac{E_{real}^2}{(1/m)^2} \tag{5}$$

with E_{real} and $P_{abs,real}$, the incident electric field strength and absorbed power under realistic exposure conditions.

FDTD is a time-domain method, which has to be terminated after a certain simulation time, which can be quantified in number of periods of the RF-EM waves that is incident on the insect. After a certain number of simulation periods of the incident plane wave, P_{abs} converges

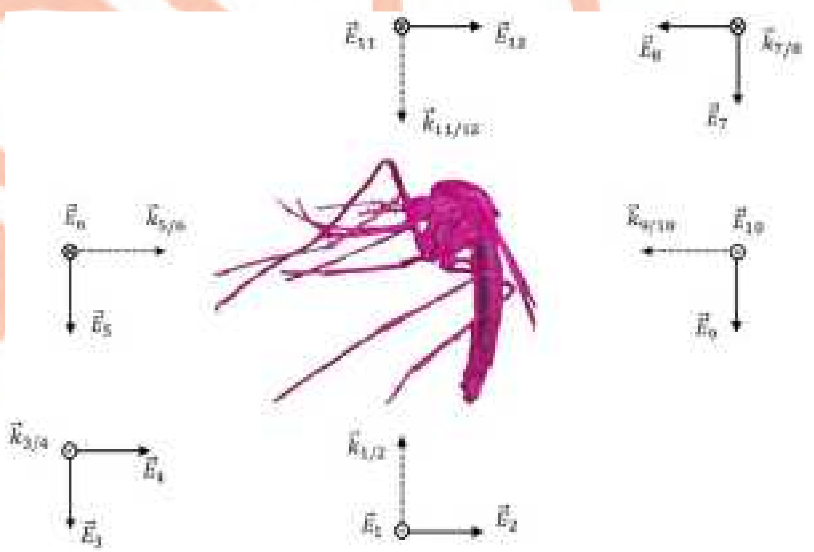

Fig 1. An overview of 12 plane waves in the simulation set up. 6 directions × 2 polarizations. The wave vector is indicated with the dotted arrow and the electric field with a solid arrow.

https://doi.org/10.1371/journal.pcbi.1009460.g001

to a steady state. The number of periods required to reach the steady state depends on the size of the simulation domain relative to the simulated wavelength. For a smaller wavelength, more periods will be needed to cover the complete domain. The number of periods were 7 and 35 at 2 and 240 GHz, respectively, while for the other frequencies the number of periods was between 10 and 35. The simulation time was always higher than twice the maximum body length of the mosquito, divided by the wavelength.

In the FDTD method, a grid is imposed to the simulation domain discretizing the volume of interest, including the mosquito. The grid step size was defined according to a trade off between a shorter simulation time for large grid step sizes and a better spatial resolution for smaller grid step sizes. Further, the grid step size should be minimum 1/10 of the wavelength. [34]. The smallest wavelength $\lambda/\sqrt{\epsilon_r}$ is 573.5 μm at 240 GHz, while all mosquitoes were discretized in voxels of 25 μm.

The FDTD technique used in this paper also has its limitations. The method is based on the discretization of the differential form of Maxwell's equations [34]. The evolution over time of EMFs is discretized in temporal steps and the simulated space is discretized into voxels. The smaller the voxels and time intervals, the more realistic the simulations are. However, simulations are always an approximation of reality. The simulation domain cannot be infinitely large, and consequently boundary conditions are used to limit the domain. The boundary conditions used in our simulations are Uniaxial Perfectly Matched Layers, which mimic an infinitely extended free space. The simulations further rely on accurate dielectric properties and 3D models.

Results

3D models

Three dimensional numerical models of three female and three male mosquitoes were constructed from micro-CT scans of real mosquitoes. Using the micro-CT technique, internal structures of the insect under investigation could be distinguished, and a high resolution is achieved. However, fine structures such as parts of the wings, scales or other fine structures, were not distinguishable enough from the surrounding air. Hence, they could not be included in the model. Small details on the thorax, abdomen, and head were manually added on slices based on unsegmented features in the raw data. On the abdomen, many fine structures were not captured, especially for the male models, and were impossible to reconstruct completely. During handling, also loss of legs occurred for some samples. Fig 2 shows the top, side and back view of all six mosquitoes as well as a more detailed view of mosquito M1 for the triangulated model and the model after voxelating (voxel length 25 μm).

Table 2 lists an overview of the volumes and dimensions of the mosquito models. The volumes are taken after voxelating with a voxel length of 25μm. The body length of the mosquitoes is measured from the pronotum to the end of the abdomen. The diagonal given in the table, is the diagonal of the bounding box containing the whole insect. This diagonal strongly depends on the presence of legs in the model, therefore the body length is the main representation of the mosquito dimensions in this paper.

Dielectric properties

The insect are approximated as homogeneous models in the simulations, with no differentiation between different tissue and so only one set of dielectric properties are used for the material for every frequency. Fig 3 shows the measured permittivity and conductivity of the mosquito-mixture for frequencies between 5–67 GHz, and extrapolated to 2–300 GHz. The

loss factor (imaginary part of the complex permittivity) was found from the conductivity (Eq 2) and is also given in Fig 3. The extrapolation was done using the Debye relaxation model with two characteristic relaxation times, the resulting parameters for the dielectric curves are given in Table 3. The R^2 for the Debye fit to the measured data is 0.99995 for the real part of the permittivity and 0.999994 for the conductivity with two relaxations, compared to 0.996 and 0.992 respectively for one relaxation time.

The real part of the permittivity decreases with increasing frequency and the conductivity increases with increasing frequency. The loss factor has a local maximum around the frequency corresponding to τ_2, the most prominent relaxation in this frequency range. At lower frequencies a decreasing trend with increasing frequencies is apparent, originating from the static conduction term $\sigma_s/\omega\epsilon_0$.

Simulations

The amount of RF power absorbed by the 3 male and 3 female mosquito bodies in the far field is shown in Fig 4 as a function of frequency. The 3 blue and 3 red lines show the means of P_{abs} for the 12 configurations (Fig 1) in which the the 3 female and 3 male mosquitoes were exposed, respectively. The shaded areas in the graph include all 12 P_{abs} values for all 3 females (blue) and 3 males (red) of the simulations. P_{abs} increases with increasing frequency, up to 90 GHz for all six mosquitoes. At 90 GHz the highest single plane wave absorbed a power of 5.64 nW and was found for the F3 model with plane wave configuration 5 (Fig 1). At this frequency, the wavelength of the incident plane wave becomes comparable to the body length of the mosquitoes. Between 120 GHz and 180 GHz, the averages of P_{abs} for all mosquito reach a maximum, here the wavelength is smaller (2.5 mm and 1.7 mm respectively) than the body length of the insect but still comparable to the insect dimensions. Fig 4B shows P_{abs} for the 12 plane wave configurations for mosquito M1 and (c) shows the average P_{abs} for all mosquitoes at 120 GHz.

From Eq 4, it is clear that the power absorbed by the insect depends on the internal electric field strength. Fig 5 shows the normalized electric field strength (dB) in and around mosquito M1, presented in mid-sagittal cross sections. The normalization was done to the maximum electric field strength of every simulation separately. The maximal and minimal electric field strength found in the 6 GHz simulation in exposure configuration 1, was 3.53 V/m and 1.29×10^{-4} V/m respectively. For 240 GHz, this was 2.72 V/m and 2.29×10^{-2} V/m respectively. It should be noted that the abdomen does not contain a large cavity, it is the dried abdomen that is curved.

(b) The absorbed powers for mosquito M1 for the twelve different plane waves as illustrated in Fig 1. The red shaded area represents the range of absorbed power for all 12 plane waves for all male mosquitoes. (c) The bar chart shows the total absorbed power (P_{abs}) at 120 GHz, the whiskers indicate the range for all 12 plane waves.

https://doi.org/10.1371/journal.pcbi.1009460.g004

In studies that investigate absorption of RF-EMF fields, a differentiation between absorption in different body parts is often made. In the case of humans, for example, the international committee on non-ionizing radiation differentiates between RF-EMF exposure of the torso and head on the one hand and the limbs on the other hand [35]. This approach is followed because exposure or heating of different body parts might results in different outcomes. Using the simulations performed in this study, the different parts of the mosquito body can be considered separately as well. The absorbed power in the head, thorax, and abdomen were calculated and averaged over their respective volumes. The volumes selected as the body part varied slightly for simulations at different frequencies due to different grid settings, and thus the volumes varied slightly as well. The volume of the head, thorax, and abdomen were 0.91 ± 0.01 mm^3, 4.30 ± 0.03 mm^3, and 2.91 ± 0.05 mm^3 for M1, respectively. The average P_{abs} for M1 and F1 are given in Fig 6. The head and abdomen have a similar behaviour, while there is more

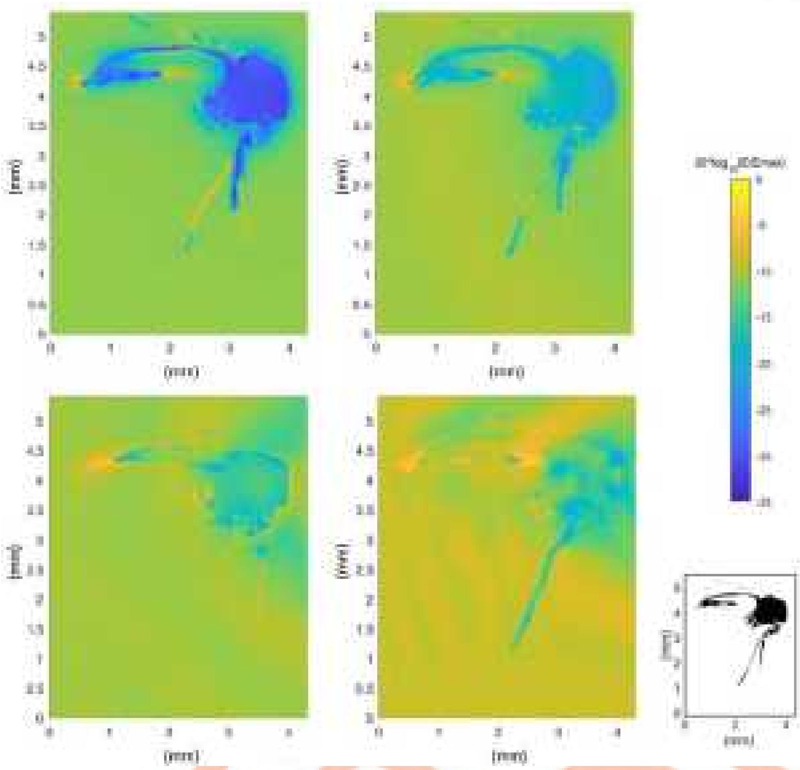

Fig 5. Normalized electric field strength in and around a mosquito. Electric field strength (dB) normalized to the maximal electric field strength of the simulation (E_{max}) in the cross sections of mosquito M1 at 6 GHz (top left), 60 GHz (top right), 120 GHz (bottom left) and 240 GHz (bottom right). Configuration 1 (Fig 1) was used for all simulations. The bottom right panel shows a cross section of the mosquito.

https://doi.org/10.1371/journal.pcbi.1009460.g005

averaged P_{abs} at higher frequencies for the thorax. For the female mosquito, the thorax and abdomen averaged P_{abs} are slightly higher.

Effect of model variations. The P_{abs} is slightly larger for the three females than for the three males (KS-test, $p<0.05$). This can partly be explained by the larger volume and body size of the females [36] as seen in Fig 2.

In addition to the sex-related differences, the models varied in number of legs still attached to the specimens. Model M1 had 6 legs, while F3 had only two. The influence of the presence of the legs is investigated by removing a hind leg of M1 and by removing all six legs of M1. Simulations were again done at 120 GHz for the 12 different plane waves and compared to the results for the original six-legged M1, which had a mean P_{abs} of 3.40 nW for the 12 plane waves at 120 GHz. When the hind leg of M1 was removed, the volume of the mosquito model was reduced to 97.4%, and the P_{abs} mean decreased to 3.31 nW with a maximal relative deviation of 3.39% for the 12 simulations. For the case where all legs were removed, the model volume was reduced to 86.0% of the original model and the mean of P_{abs} decreased to 2.91 nW, with a maximal relative deviation of 20.92% for the 12 simulations.

Uncertainties of simulation. It becomes clear from Fig 4 that the angle of incidence and polarization of the plane waves, have an impact on the absorbed power. The 12 plane waves seen in Fig 1 are orientated along the main axis of the insects. Real life exposure situations are not limited to those 12 configurations and simulations with 30 random orientations and polarizations were added at 60 GHz for M1. None of these simulations resulted in a P_{abs} outside the

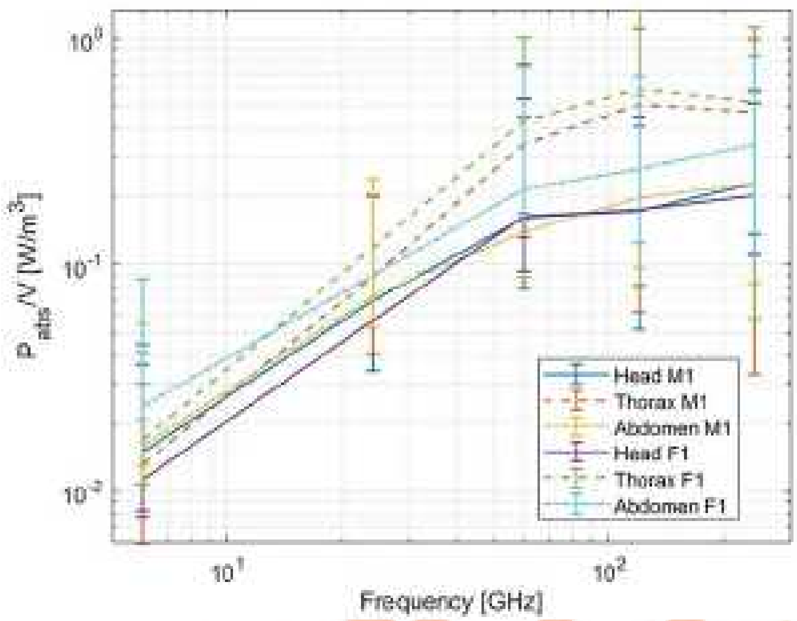

Fig 6. Averaged absorbed power as function of frequency in the head, thorax, and abdomen of a yellow fever mosquito For an incident field strength of 1 V/m. Averaged over the volumes of the body part for mosquitoes M1 and F1.

https://doi.org/10.1371/journal.pcbi.1009460.g006

interval of the 12 plane waves along the main axes. The mean of P_{abs} for the 30 simulations was 2.31 ± 0.36 nW, which is comparable to the mean of P_{abs} for the 12 plane waves 2.37 ± 0.59 nW, for E_{inc} = 1 V/m.

Another element contributing to the uncertainty in the simulations is the grid step size or voxel size. The voxel size of the mosquito models was set to 25 μm, and is larger than the resolution of the mosquito models. To confirm the chosen grid step size is small enough, 12 simulations (six incident angles × 2 polarizations) with a smaller grid step size of 15 μm were performed at 240 GHz. At this frequency, the wavelength is the smallest and the voxel size becomes more important. Compared to the case with 25 μm, P_{abs} for the 15 μm has a maximal relative deviation of 2.61% and has a mean P_{abs} of 3.49 nW (versus 3.51 nW). This smaller voxel size has a smaller impact on P_{abs} than the incident angle and polarization, hence the grid step size of 25 μm can be considered sufficient for these simulations.

The measurement of the dielectric properties was done for two samples of a mosquito-mixture, with a maximal relative deviation between the two samples on the dielectric properties of 4.04% and 5.81% for ϵ' and σ respectively. To establish the influence of the dielectric parameters on the simulation results, four extra sets of 12 simulations were executed for a plane wave of 60 GHz ($\epsilon' \pm 0.0404 \times \epsilon'$, $\sigma \pm 0.0581 \times \sigma$). A maximal relative deviation on P_{abs} was found to be 5.41%, which again is smaller than the influence of incident angle and polarization.

Discussion

3D Models

We used micro-CT scanning to obtain spatially accurate mosquito models that had a sufficient resolution to model exposure at 240 GHz (grid step = 25 μm). The micro-CT approach has the advantage of being non-invasive and providing information of the insect's internal anatomy

[37]. However, dried specimens were used for the micro-CT scans to reconstruct the models in this study and the models were made homogeneous with no distinction between different tissues in the mosquito. Real mosquitoes will have different tissues and the position, size, gradients and edges of these tissues will influence the power absorption. In [17, 18] a similar technique was used for different life stages of the Western Honeybee, an Australian Stingless Bee, a Desert Locust and a Dor Beetle.

Other possible techniques for imaging of insects exist [38, 39], but are not all suitable for reconstruction of 3D models. An example of 3D reconstructions of insects is given in [40], where a camera and different angles and focal depths were used with shape-from-silhouette. In [41], a shape-from-motion approach was used for capturing insects' surface geometries and colours. They were able to capture details such as hairs for different insects and a 3D mosquito model from a *Culex pipiens L.* was retrieved using this method. However the resolution of both techniques was lower than for the 3D mosquito models used in this study. In [42] 3D models of insects constructed by a structured light scanner also showed less details of the surface geometries than for a (Synchrotron Radiation) micro-CT method. To the best of our knowledge, no other 3D model of a yellow fever mosquito exists that has been constructed from data of a real insect. Moreover, our mosquito models are based on micro-CT scannings that have a high resolution in comparison to most existing models.

However, the micro-CT method has its limitations: using this imaging technique, some details such as scales and thin antennae were not distinguishable from air in the 2D cross-sections and are thus not part of the 3D model. Additionally, the scanned insects need to be immobilized or dead. In the case of dried species, small deformations can occur compared to living mosquitoes. Nevertheless, the 3D models based on mosquito specimens are detailed and can be considered a good representation of life mosquitoes. Our models can be used to obtain realistic values of absorbed power and inspection of actual E_{int} distributions in simulations.

Dielectric properties

Dielectric properties of the yellow fever mosquito mixture were obtained using coaxial-probe measurements from 5–67 GHz. Previous studies [6, 23, 24, 43–46] have also investigated dielectric properties of insects in this frequency range, some of these values for ϵ' and ϵ" are given in Fig 7, together with the dielectric properties from this study for comparison.

The dielectric properties are slightly smaller for the yellow fever mosquito than most of the other insects measured in [6, 23, 24, 45, 46] for the same frequency range, but are overall comparable, see Fig 7. The permittivity curves exhibit similar behaviour to each other and to the Debye model, with ϵ' decreasing with increasing frequency. From 6 GHz up to higher frequencies, the ϵ" shows a typical Debye relaxation response, for τ_2 a local maximum is visible in Fig 3 around 9.4 GHz. This same behaviour was also observed in previous studies on insect dielectric properties: a local peak is also found around 9.4 GHz for the red flour beetle and the lesser grain borer in [23], around 15.81 GHz for the Colorado potato beetle in [24] and between 10–15 GHz for the larva of the palm weevil in [44]. At lower frequencies, a decreasing trend with increasing frequencies is apparent for our model (Fig 3) and the measurements presented in [23, 24, 46], originating from the static conduction term.

When two relaxation times are assumed in the Debye fit of the the dielectric properties, the curves ϵ' and ϵ" are well in agreement with the measurements, better than for the case of only one relaxation. The parameters of the Debye model given in Table 3, are similar for both curves, a confirmation that the two relaxation Debye model is suitable. For simulations with frequencies below 5 GHz or above 67 GHz, the dielectric properties are taken from a extrapolation using these parameters.

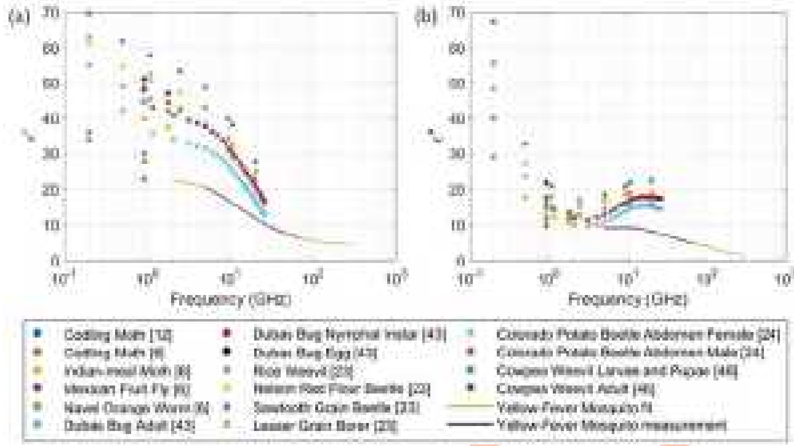

Fig 7. (a) Real and (b) imaginary part of relative permittivity. Given for insects in other studies [6, 12, 23, 24, 43, 45, 46] and for the yellow fever mosquito.

https://doi.org/10.1371/journal.pcbi.1009460.g007

Numerical simulations

The absorption of RF power by the mosquito is dependent on the electric field in and around the insect, described by Eq 4. At 6 GHz, the wavelength of the incident wave is considerably larger than the insect and will mostly refract and not penetrate the insects' body. At this frequency, it can be seen in Fig 5 that the electric field strength is higher at the boundaries of the insect than inside, making the surface area of the insect an important factor in the power absorption. For increasing frequency up to 120 GHz, EMFs penetrate the insect more efficiently, contributing to an increasing absorption. This is visible in Fig 4. At a frequency of 90 GHz, the increase in absorbed power becomes smaller and the maximum value of P_{abs} is found for mosquito F3 in configuration 5 (Fig 1) with the electric field parallel to the body length of the insect. The incident wave with a frequency of 90 GHz corresponds to a wavelength of 3.33 mm (in free space), comparable to the body length of the insects (Table 2). In this frequency region, whole-body or partial-body resonance [3] occurs causing a higher absorption of the EMFs. The electric field will penetrate more in the insect (Fig 5) at this higher frequency compared to a lower frequency, 6 GHz, inducing more RF absorption inside the insect (Eq 4). On the contrary at 240 GHz, the penetration depth is expected to decrease [18] in comparison to 90 GHz, and spots with lower electric field strength are found in the (middle of the) thorax. Simultaneously, the conductivity increases with increasing frequency as shown in Fig 3. The combination of these two counteracting effects cause the P_{abs} to slightly decrease at 240 GHz in comparison to 90 GHz. At frequencies below 90 GHz, incident electric fields oriented along the same axis induce a P_{abs} in the insect, which are nearly equal to each other. This can be seen in Fig 4B where the P_{abs} under exposure with the electric field along the three main axes show three bundles of four coinciding values at these frequencies below 90 GHz. The relative order of P_{abs} induced by the polarization below 90 GHz is altered for higher frequencies and the polarization responsible for lowest or highest P_{abs} varies.

At 6, 60 and 120 GHz, the mean P_{abs} for an incident field strength of 1 V/m, of all mosquitoes and all 12 plane waves, are 0.165 nW, 2.64 nW and 3.59 nW respectively. For a change of 6 GHz to 60 GHz with the same incident field strength (1 V/m), this translates into a power absorption that is 16 times higher. For a change from 6 GHz to 120 GHz this increase will be even greater, the P_{abs} is 21.8 times higher. In the current networks, frequencies up to 6 GHz are used, with most telecommunication frequencies at $\leq$ 2 GHz [1]. Future networks that emit

EMFs at higher frequencies with a same incident power, will consequently lead to more absorbed power by yellow fever mosquitoes. In reality, the incident electric field strength will vary in time and position. Currently, 5G networks have started being installed and the typical values of the electric field strengths are not yet known for all situations. From measurements at 3.5 GHz in [47] a maximal electric field strength of 4.9 V/m was found at their measurement location, after scaling to a input power of 200 W on the base station. In simulations designed to decrease exposure in a 5G networks presented in [48] at 3.7 GHz, the authors of [48] expected electric field strengths between 0.0068 and 0.0233 V/m in a crowded environment. The values can thus be lower or higher than the 1 V/m that was used in the simulations with the mosquitoes (see Fig 4). Additionally, the exposure in the environment will be limited by (inter)national guidelines and legislation. Many of these are based on the ICNIRP guidelines [35]. The ICNIRP reference level is 61.5 V/m at 2 GHz for the general public when averaged over 30 minutes, which is 61.5 times larger than the electric field strength used in the simulations in this manuscript. For larger frequencies, up to 300 GHz, the guidelines specify a limit on the incident power density, which is 10 W/m2, instead of the incident electric field strength. The absorbed powers in this work can be rescaled to other incident electric field strengths using Eq 5. Further, dielectric heating will be caused by exposure at multiple frequencies simultaneously. Absorbed RF power is a proxy for dielectric heating, which can have an effect on e.g. behaviour, development and dielectric heating of mosquitoes might influence their spread. In order to assess dielectric heating accurately, more precise measurements of A. Aegypti's mass and specific heat capacity would be necessary.

In [17], similar simulations were performed on four insects which resulted in a similar power absorption dependency on frequency. The largest absorption occurred at frequencies with a wavelength comparable to the insect's size. The smallest insect under consideration, the Australian Stingless Bee, experienced less power absorption compared to the larger insects for all frequencies, with a maximal P_{abs} at 60 GHz of $\approx$ 30 nW. The body lengths of the Australian Stingless Bee models are comparable to the length of the mosquitoes, however the peak of maximal absorption is at a lower frequency and P_{abs} is higher than for the mosquitoes. This indicates the necessity of insect-specific simulations and measurements of dielectric properties. Going from 6–60 GHz (the absorption peak), meant for the Australian Stingless a higher P_{abs} by a factor $\approx$ 23. For the mosquitoes, this difference (×16) is smaller, however when looking at 6–120 GHz, i.e. looking at an increase from 6 GHz up to the plateau around the maximum P_{abs}, a similar increase of a factor ×21.8 is seen. For the other insects in [17], the absorption peak is found at even lower frequencies (6, 12 and 24 GHz). In [18], different life stages of the Western Honeybee were subjected to similar simulations, also here a similar power absorption dependency on frequency was observed and absorbed powers were again higher than for the mosquitoes. Going from 6 GHz to higher frequencies in [17, 18], meant going up in absorbed power by the insect, except for the Honey bees that had an absorption peak at 6 GHz.

The power absorption is not proportionally distributed over the body, and thus not only the whole-body absorbed power is considered, the mosquito body is divided in three parts without the legs and the absorbed power is averaged over this body part. Fig 6 shows the averaged head, thorax and abdomen P_{abs} for M1 and F1. This gives insight in the absorption in the different parts of the insect. Abdomen and head have a similar average absorption, and the thorax has a considerably larger averaged absorption at 60 GHz and higher. The thorax has a clearly higher volume-averaged RF absorption than the head or abdomen. We attribute this difference to the shape, the mosquito models have a thorax that can be approximated as a solid sphere, while the abdomen and head have a larger surface/volume ratio than the thorax.

Effect of model. From Fig 4, a larger P_{abs} is found for the three female mosquitoes for all frequencies, than for the three male mosquitoes. When comparing the volume of the mosquitoes in Table 2, it is clear that the female mosquitoes under consideration, have a larger volume and thus can absorb more RF power. When averaging the P_{abs} over the volume of the whole body, the three female mosquitoes still show a higher RF absorption than the three males. The radar cross section does not scale linearly with volume. The female mosquito is not only larger, but differs also slightly in morphology from the male mosquito [36], which also induces a difference in P_{abs}. Further, the models used in the simulations, do not all have the same amount of legs, which influences the absorbed power. Absorbed power in models with less than 6 legs, would have a higher absorbed power in the realistic case of six legs.

Uncertainties of simulations. The FDTD technique makes use of a three dimensional grid and the mosquito models need to be discretized. The voxels used in all simulations were 25 μm. Smaller voxels result in more reliable results, however simulation times will run up. The influence of a smaller voxel size and the influence of the uncertainty on dielectric parameters are smaller than the effect of incidence angle and polarization. It follows that a choice of 25 μm for the voxels is sufficient. The impact of incidence angle and polarization on the P_{abs} is visible from the bar chart in Fig 4, where the whiskers indicate the total range of P_{abs} for the 12 simulations. To verify that these 12 plane waves represent the range of possible absorbed powers, 30 simulations with random orientations and polarizations were considered at 60 GHz. No simulation resulted in a value outside the range of the earlier 12 plane waves.

Strengths and limitations

This paper contributes to the state of the art in different aspects. First of all, six detailed 3D models of the yellow fever mosquito were designed by means of micro-CT scans. The models are, to our knowledge, the first models based on real mosquitoes with a high spatial resolution. Second, the dielectric properties of homogenised yellow fever mosquitoes were measured for the first time, in a 5–67 GHz range. The use of the model obtained from real mosquitoes and the use of dielectric properties of the insect in question, result in more accurate simulations. Advantages of using simulations as opposed to experiments, is the ease in exploring different setups and frequencies. The RF exposure of mosquitoes were numerically simulated, leading to first-time insights on absorbed power by yellow fever mosquitoes at frequencies in 4G and the future 5G mm-waves.

The methods used in this study also come with limitations. The micro-CT scan, despite leading to high resolutions and insight in internal structures of the insects, did not capture the wings and certain thin instances of the mosquitoes. The models were made from dried unfed dead mosquitoes, and no distinction was made between different tissues of the insect. Real mosquitoes will have different tissues and the position, size, gradients and edges of these tissues will influence the power absorption. The dried species can vary slightly from living mosquitoes in form. The dielectric properties below 5 GHz and above 67 GHz, are not measured but acquired by extrapolation. In the simulation environment, the model is discretized in voxels and the simulations are only an approximation of reality. The limitations of the simulations further lie in the uncertainties that accompany the FDTD technique and the use of a limited amount of plane waves representing the far-field. Uncertainties on parameters in simulation settings and random angle of incidence were adopted in extra simulations to explore these limitations. However the absorbed power is a proxy for dielectric heating, values of actual heating are outside the scope of this paper.

Future work

Future work will consist of the study of other life stages of the mosquito exposed to RF-EMF exposure. Another step forward will be investigating heterogeneous models of the insect, with different dielectric properties for different tissues. Experiments concerning RF-EMF absorption, scattering and measurements of heating (by e.g. infrared cameras), can verify current results and give more insight in the matter. Also measurements on living mosquitoes will enable us to study the influence of RF EMFs on the insect. Further, other insects can be used in similar simulations, to have a more complete view of RF-EMF absorption of insects exposed to 4G and 5G telecommunication and size dependency of absorbed power.

Conclusion

By creating six high resolution 3D models and by measuring dielectric properties from real mosquitoes using a coaxial-probe technique, realistic FDTD simulations were possible for far field exposure between 2 and 240 GHz. The absorbed RF power P_{abs} for this insect is lower than for other insects, with a maximum of 5.64 nW for an incident field strength of 1 V/m. Female mosquitoes absorb more power than male mosquitoes, while the body part absorbing most power is the thorax. The distribution of the electric field in and around the mosquito showed a higher field strength in the insect for 120 and 240 GHz than for 6 GHz. The P_{abs} for EMFs with a frequency of 60 GHz was 16 times larger than for 6 GHz, with the latter frequency the upper limit of current telecommunication networks. For 120 GHz, this increase is even larger compared to 6 GHz, with a factor 21.8. Around this frequency, the maximum in RF EMF absorption was observed for all mosquitoes. In the future, the carrier frequency of telecommunication systems will also be higher than 6 GHz. This will be paired with higher absorption of EMF by yellow fever mosquitoes, which can cause dielectric heating and have an impact on behaviour, development and possibly spread of the insect.

Sperm quality
Toxicity

A B S T R A C T

Potential suppression of fertility due to mobile phone radiation remains a focus of researchers. We conducted meta-analyses on the effects of mobile phone radiation on sperm quality using recent evidence and propose some perspectives on this issue. Using the MEDLINE/PubMed, Embase, WOS, CENTRAL, and ClinicalTrials.gov databases, we retrieved and screened studies published before December 2020 on the effects of mobile phone use/mobile phone RF-EMR on sperm quality. Thirty-nine studies were included. Data quality and general information of the studies were evaluated and recorded. Sperm quality data (density, motility, viability, morphology, and DFI) were compiled for further analyses, and we conducted subgroup, sensitivity, and publication bias analyses. The pooled results of human cross-sectional studies did not support an association of mobile phone use and a decline in sperm quality. Different study areas contributed to the heterogeneity of the studies. In East Europe and West Asia, mobile phone use was correlated with a decline in sperm density and motility. Mobile phone RF-EMR exposure could decrease the motility and viability of mature human sperm *in vitro*. The pooled results of animal studies showed that mobile phone RF-EMR exposure could suppress sperm motility and viability. Furthermore, it reduced sperm density in mice, in rats older than 10 weeks, and in rats restrained during exposure. Differences regarding age, modeling method, exposure device, and exposure time contributed to the heterogeneity of animal studies. Previous studies have extensively investigated and demonstrated the adverse effects of mobile phone radiation on sperm. In the future, new standardized criteria should be applied to evaluate potential effects of mobile phone RF-EMR dosages. Further sperm-related parameters at the functional and molecular levels as well as changes in biological characteristics of germ cells should be evaluated. Moreover, the impact of mobile phone RF-EMR on individual organs should also be examined.

1. Introduction

Mobile phones produce a type of non-ionizing radiation termed radio frequency electromagnetic radiation (RF-EMR; Belpomme et al., 2018). The increasing popularity and use of mobile phones have raised concerns on whether RF-EMR can affect male sperm quality (Jalilian et al., 2019), and the current consensus in the general public is that mobile phone RF-EMR is a major risk factor of decreased sperm quality. However, the results of current research are contradictory, and whether mobile phone RF-EMR exposure decreases male sperm quality remains an unresolved issue in the scientific community. For instance, one study showed that sperm deformation rates in men increased with increasing mobile phone

usage time (Agarwal et al., 2008), whereas a different study found no such a correlation (Erogul et al., 2006). Mobile phone radiation was reported to suppress sperm motility and viability (Mailankot et al., 2009; Ghanbari et al., 2013), whereas some different studies suggested that this type of radiation didi not affect sperm density, motility, and viability in rodents (Dasdag et al., 2013; Trosic et al., 2013). In 2014, Liu et al. pooled the results of four cross-sectional studies, four human sperm *in vitro* studies, and four animal studies and attempted to conduct a meta-analysis on the relationships of mobile phone use and sperm quality in terms of the three aforementioned aspects (Liu et al., 2014). The results of this meta-analysis did not suggest that mobile phone usage was associated with changes in human sperm quality; however, direct mobile phone RF-EMR exposure could reduce human sperm motility and viability *in vitro*. Moreover, the results of animal experiments suggested that mobile phone RF-EMR exposure could decrease sperm density and motility (Liu et al., 2014). At approximately the same time, Adams et al. conducted a meta-analysis on human sperm quality, which included 10 studies (five cross-sectional studies and five *in vitro* studies of human sperm) and found that mobile phone RF-EMR exposure could affect human sperm motility and viability (when the results of the two aforementioned study types were pooled; Adams et al., 2014). The additional subgroup analysis conducted by Adams et al. using these limited studies only supported that mobile phone RF-EMR did not decrease sperm density *in vitro* (Adams et al., 2014). These previous studies pooled the findings of earlier studies, formulated some hypotheses, and revealed preliminarily relationships between mobile phone RF-EMR exposure and male subfertility. However, owing to large differences in experimental conditions among the included studies, the meta-analyses by Liu et al. and Adams et al. were highly heterogeneous in terms of results. Moreover, because of the small number of studies available for analysis, further heterogeneity analysis was limited. Thus, both research groups proposed that their preliminary conclusions should be further examined and that their hypotheses should be further tested to elucidate the effects of mobile phone RF-EMR on male fertility. Taken together, additional data analyses are required to test the effects of mobile phone RF-EMR exposure on sperm quality.

In the past six years, the rapid advancement of communication technology and the advent of 5G technology has led to increased cell phone use and subsequent higher exposure rates to associated RF-EMR. Therefore, it is imperative to gain scientific understanding of the effect of mobile phone RF-EMR on male fertility (Choi et al., 2018; Simkó and Mattsson 2019). Whether mobile phone RF-EMR and other RF-EMR types emitted by wearable devices or the "Internet of Things" may exert reproductive toxicity has garnered social attention and has attracted research interest. Many new studies using different experimental conditions have been published, and we conducted a meta-analysis based on these studies to examine the impact of mobile phone RF-EMR on sperm quality and to test some of the hypotheses proposed in previous studies. Our analyses may elucidate the progress in the research on the relationship of mobile phone use and male fertility. Furthermore, we discuss personal views on the topic to provide suggestions for future research.

2. Methods

2.1. Search strategies

This meta-analysis was conducted according to the Preferred Reporting Items for Systematic Reviews and Meta-Analyses guidelines, the Meta-analyses of Observational Studies in Epidemiology guidelines, and the guidelines for reporting animal research. We searched the MEDLINE/PubMed, EMBASE, Web of Science (WOS), Cochrane Central Register of Controlled Trials (CENTRAL) and ClinicalTrials.gov. databases for respective studies on this topic.

A mesh was applied to define the subject heading, which was supplemented and simplified to achieve a more accurate literature retrieval. The search strategy in MEDLINE/PubMed was as follows:

("cell phone*"[Title/Abstract] OR "cellular phone*"[Title/Abstract]) OR "cellular telephone*"[Title/Abstract]) OR "mobile phone*"[Title/Abstract]) OR "mobile telephone*"[Title/Abstract]) OR "electromagnetic"[Title/Abstract]) AND (("sperm*"[Title/Abstract] OR "semen"[Title/Abstract]) OR "Seminal"[Title/Abstract]).

We searched for studies conducted before December 2020. The search strategies employed on the EMBASE and WOS databases are shown in Supplement 1. We also screened references in respective articles to identify other potential studies.

2.2. Inclusion and exclusion criteria

The inclusion criteria were as follows: 1. human cross-sectional studies, human sperm studies *in vitro* (i.e., experiments were conducted on ejected semen *in vitro*), and animal experiments on the relationships of mobile phone use/mobile phone EMR and sperm quality/semen quality; 2. associated studies with a control or comparison group; 3. associated studies with semen analysis/sperm quality analysis; 4. a specific absorption rate (SAR) of mobile phone RF-EMR below 2 W/kg for human sperm studies *in vitro* and animal studies.

The exclusion criteria were as follows: 1. studies investigating the relationship of mobile phone base stations, radar EMR, extremely low EMR, wireless fidelity, mobile phone RF-EMR jammers, and joint electromagnetic fields with male sperm quality; 2. studies investigating the effects of mobile phone RF-EMR exposure on pregnancy; 3. animal studies *in vitro* (i.e., studies on biological changes in various germ cell lines such as GC2 and TM4, but lacking data on mature sperm quality); 4. studies containing data values with incorrect decimal points; 5. studies in which the mean or standard deviation could not be calculated based on the accessible data; 6. special article types, including reviews, meta-analyses, comments, statements, and retracted articles.

2.3. Quality assessment

We used the Joanna Briggs Institute Practical Application of Clinical Evidence System (JBI) list to evaluate the included human cross-sectional studies (Laidsaar-Powell et al., 2019). We referred to the method proposed by Liu et al. and evaluated the quality of human sperm *in vitro* studies based on four parameters (Liu et al., 2014): representativeness of subjects, type of the radiation exposure device, comparability of the exposure and the control group, and representativeness of evaluation indices. The scoring system ranged from 0 (low quality) to 4 (high quality). We applied the Collaborative Approach to Meta-Analysis and Review of Animal Data from Experimental Stroke (CAMARADES) list to evaluate animal studies (Tong et al., 2019). Details are provided in Supplement 2.

2.4. Data extraction

Basic information of the included studies was extracted according to different study types. Data on sperm quality data including sperm density, motility, viability, morphology, and DNA fragmentation index (DFI) were pooled. Sperm quality data of rats and mice were pooled separately.

2.5. Statistical analyses

Meta-analyses were performed using RevMan 5.3. Standardized mean differences (SMD) and mean differences (MD) were used to analyze sperm quality. Cochran's Q test was applied to test heterogeneity, after which at $P > 0.1$, a fixed effects model was fitted, and at $P \leq 0.1$, a random effects model was fitted. Heterogeneity is represented by I^2. Subgroup analyses were performed to analyze the origin of heterogeneity using RevMan 5.3. Regarding human cross-sectional studies, we performed a subgroup analysis based on study area, exposure time, and evaluation method. For animal studies, subgroup analyses were conducted with respect to animal age (younger or older than 10 weeks), radiation exposure device (mobile phone or simulator), animal status during modeling (restrained or unrestrained), and modeling time (short-term exposure at < 140 h or long-term exposure at > 140 h).

A one-by-one exclusion method was applied to the sensitivity analysis. For parameters included in more than seven studies, we applied a funnel chart, Egger's test, and Begg's test using Stata 16.0 to evaluate potential publication bias.

Literature retrieval, quality assessment, and data extraction were independently completed by two reviewers. If the opinions were inconsistent, the reviewers consulted with each other or with a third party.

3. Results

3.1. Search results

A flow chart of the screening process is shown in Fig. 1. In total, 1073 studies were retrieved, and after screening, 137 studies remained for full-text reading; of these, 98 studies were excluded, and 39 studies were included, which comprised 5 human cross-sectional studies, 8 human sperm *in vitro* studies, and 26 animal studies (20 studies on rats and 6 studies on mice) for meta-analyses. These 39 studies included results on sperm quality analysis of 2567 men of childbearing age (including 225 semen samples of men of childbearing age for sperm experiments *in vitro*) and 836 epididymal semen samples of animals (583 rats and 253 mice). Full texts of five studies could not be obtained even after contacting the respective authors by e-mail. One study with a data value with an incorrect decimal point mark and one study in which the standard deviation could not be calculated were excluded during screening; despite inquiring with the respective authors by e-mail, no further information was obtained.

3.2. Basic information

The basic information of the included studies is shown in Tables S1, S2, and S3.

3.3. Quality evaluation

As shown in Table 1, the JBI score of the human studies ranged from 9 to 15, and only in one study was the JBI score below 10, whereas in four studies, it was higher than 10. The JBI score for human sperm *in vitro* studies ranged from 8 to 10; in one of these studies, the JBI score was 8, while in seven studies, the JBI score was 9. Regarding animal studies identified through the CAMARADES list, the JBI scores of four studies were below 7, while those of 22

3.4. Meta-analysis results

3.4.1. Research status

Currently, relevant human epidemiological studies are still lacking. Studies have been predominantly conducted using animal experiments, some of which used mobile phones, while others used RF simulators to produce mobile phone RF-EMR. Only few studies discussed effects of RF-EMR produced by 4G or 5G devices on reproductive functions, and considerable differences between evaluation methods of the actual RF-EMR dosages in the exposure area were observed. Most studies assessed the effects of RF-EMR on sperm density, motility, viability, and morphology, however, only few investigated the effects of mobile phone RF-EMR exposure on reproduction through advanced sperm function tests, sperm DFI test, and offspring quality tests. Almost all included studies investigated the effects of whole-body RF-EMR exposure on male fertility, and only few investigated the effects of local RF-EMR exposure on certain reproductive organs.

3.5. Meta-analysis results of human cross-sectional studies

3.5.1. Sperm density

As shown in Fig. 2A, five studies were included for sperm density analysis (random model; MD = −1.21 [-15.14, 12.73]; $P = 0.87$; $I^2 = 91\%$; Q test $P < 0.001$). Owing to the large heterogeneity of studies, subgroup analyses were conducted, and the results showed that I^2 decreased to 0% (Q test $P = 0.77$), P was 0.0003 in the East Europe and West Asia group, while in other regions I^2 was 97% (Q test $P < 0.0001$) and P was 0.98.

The sensitivity analysis showed that MD decreased to −7.99 (−19.13, 3.15), I^2 decreased to 79% (Q test $P = 0.003$), and P decreased to 0.16 after removing the Feijo's study. The total effect scale, I^2, Q test P, and the statistical P-value did not significantly change when other studies were removed.

3.5.2. Sperm motility

As shown in Fig. 2B, the sperm motility analysis included five studies (random model; MD = −4.77 [-11.68, 2.15]; $P = 0.18$; $I^2 = 87\%$; Q test $P < 0.0001$). Heterogeneity of the studies was high. The subgroup analysis showed that I^2 decreased to 0% (Q test $P = 0.65$), P was 0.04 in the East Europe and West Asia group whereas in the America group, I^2 was 95% (Q test $P < 0.0001$), P was 0.59. I^2 decreased to 56% (Q test $P = 0.10$), P was 0.56 in the forward motility group, whereas I^2 was 92% (Q test $P = 0.0003$), and P was 0.12 in the total motility group.

The sensitivity analysis showed that removing the study by Agarwal et al. reduced MD to −2.25 (−6.55, 2.04), and I^2 to 35% (Q test $P = 0.20$), $P = 0.30$; the analysis results did not significantly change after removing other studies.

3.5.3. Sperm viability

As is shown in Fig. 3A, the sperm viability analysis included two studies (random model; MD = −4.91 [-23.53, 13.72]; $P = 0.61$; $I^2 = 95\%$; Q test $P < 0.0001$).

3.5.4. Sperm morphology

As shown in Fig. 3B, the analysis of sperm morphology included four studies (random model; MD = −0.32 [-1.01, 0.37], $P = 0.36$, and $I^2 = 91\%$; Q test $P < 0.00001$). The subgroup analysis showed that in the East Europe and West Asia group, I^2 was 0% (Q test $P = 0.87$), and $P = 0.25$, while in the America group, I^2 was 97% (Q test $P < 0.00001$), and $P = 0.46$.

The sensitivity analysis suggested that removing the study by Agarwal et al. decreased the MD to −0.05 (−0.17, 0.07), I^2 to 0% (Q test $P = 0.44$), and P to 0.41. Removing other studies did not significantly change the analysis results.

3.6. Meta-analysis results of human sperm studies

3.6.1. Total sperm motility, viability, and density

As shown in Fig. 4, the total sperm motility analysis included seven studies (fixed model; MD = −3.56 [-5.11, −2.00]; $P < 0.00001$; $I^2 = 0\%$; Q test $P = 0.69$). The sperm viability analysis

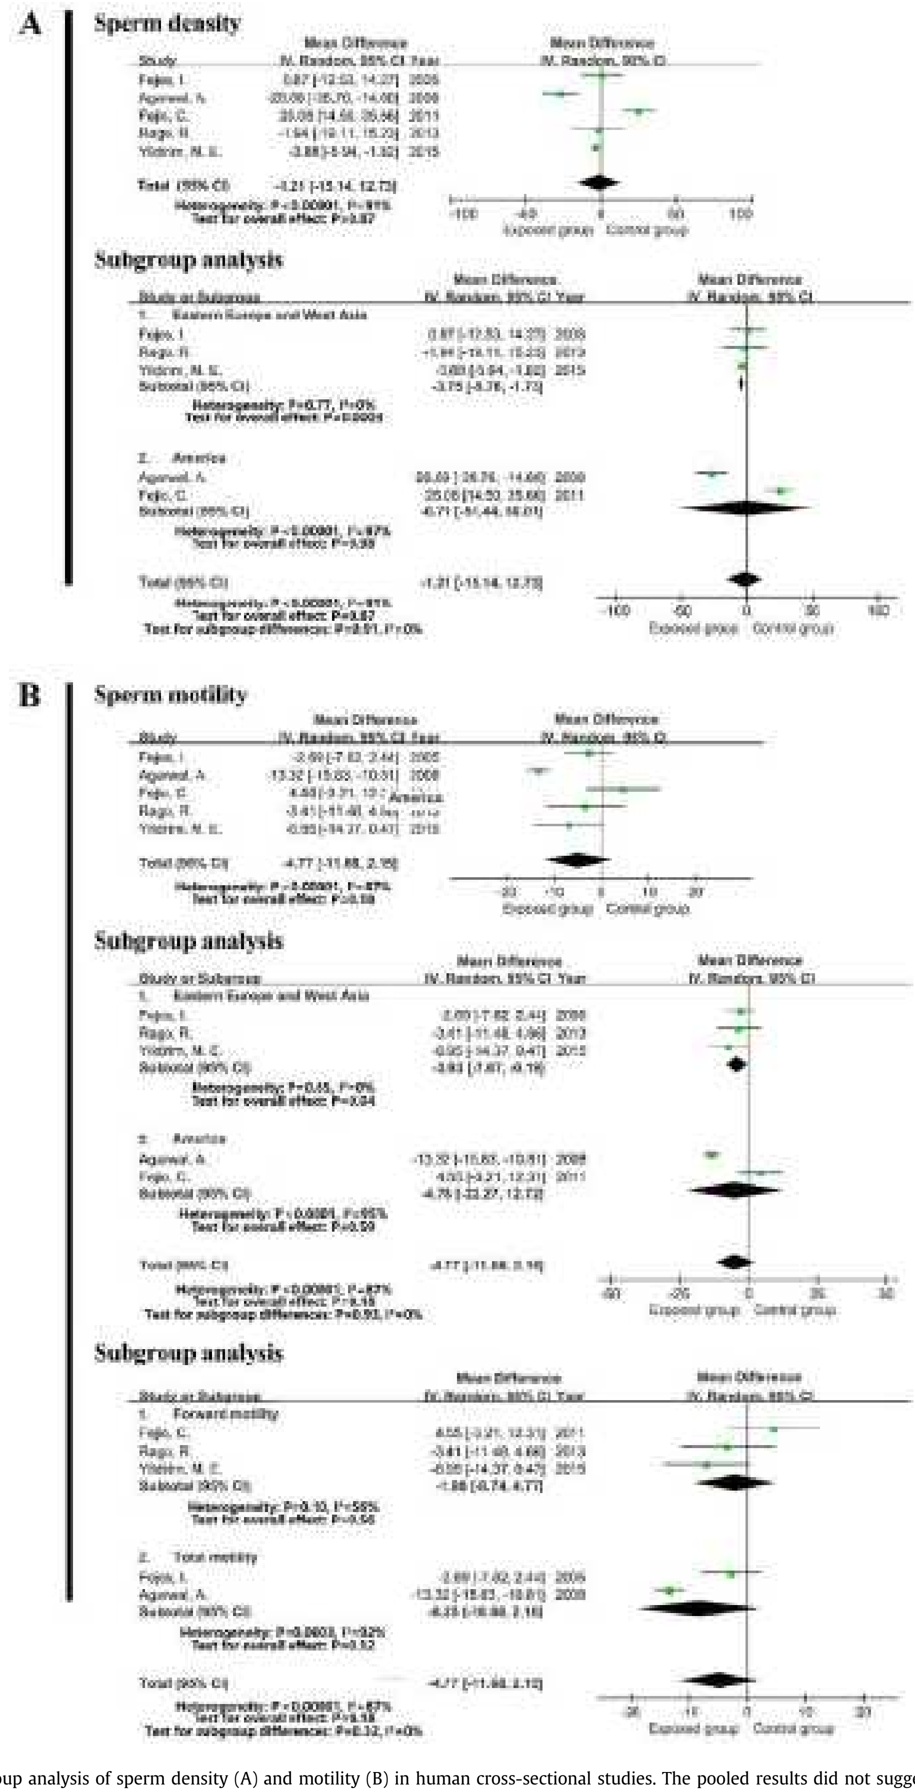

Fig. 2. Forest plot and subgroup analysis of sperm density (A) and motility (B) in human cross-sectional studies. The pooled results did not suggest that mobile phone use was associated with a decline in sperm density in humans. Study area contributed to study heterogeneity in the analyses of sperm density and motility. The evaluation method contributed to study heterogeneity regarding sperm motility analysis. Mobile phone use in East Europe and West Asia was associated with decreased sperm density and motility.

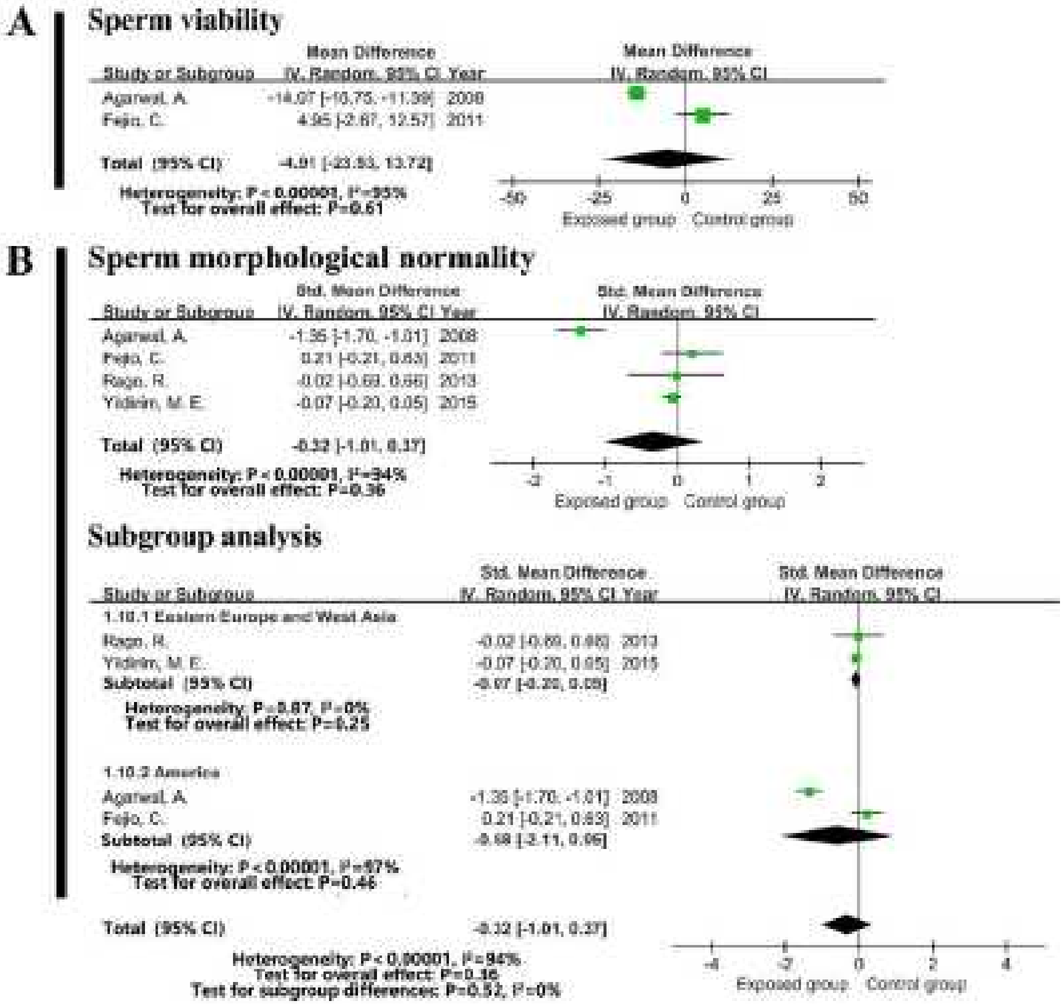

Fig. 3. Forest plot and subgroup analysis of sperm viability (A) and morphology (B) in human cross-sectional studies. The pooled results did not indicate that mobile phone use was associated with decreased sperm viability and morphology in humans. The study area contributed to the study heterogeneity of sperm morphology.

included four studies (random model; MD = −3.51 [-4.32, −2.70]; $P < 0.00001$; $I^2 = 0\%$; Q test $P = 0.74$). Three studies (random model) were included in the density analysis, (MD = −1.07 [-8.34, 6.20]; $P = 0.77$; $I^2 = 0\%$; Q test $P = 0.99$). The sensitivity analysis of total sperm motility, viability, and density showed that excluding any of the studies did not significantly affect the observed total effect scale, I^2, Q test P, and the statistical P-value.

3.6.2. Sperm DFI

As is shown in Fig. 4D, the sperm DFI analysis included two studies (random model; MD = 1.30 [-0.57, 3.18]; $P = 0.17$; $I^2 = 94\%$; Q test $P < 0.0001$).

3.7. Meta-analysis results of animal studies

3.7.1. Sperm density in rats

As is shown in Figs. 5A and 17 studies (random model) were included in the analysis of epididymal sperm density (SMD = −0.32 [-0.64, 0.00]; $P = 0.05$; $I^2 = 58\%$; Q test $P = 0.001$). The subgroup analyses are shown in Table 2. Study heterogeneity ($I^2 = 56\%$; Q test $P = 0.003$) was significantly reduced in the restrained group ($I^2 = 28\%$; Q test $P = 0.22$) and in the simulator group ($I^2 = 40\%$; Q test $P = 0.11$). In addition, subgrouping by animal age did not significantly affect study heterogeneity; however, in animals older than 10 weeks, the P-value of pooled results changed to 0.03, indicating statistical significance.

The sensitivity analysis suggested that removing any study did not change the total effect scale, I^2, Q test P, or the statistical P-value, suggesting robustness of the results. As shown in Figure S1A, the funnel plot, Begg's test (Pr = 0.06), and Egger's test ($P = 0.33$) did not suggest significant publication bias in these studies.

3.7.2. Sperm motility in rats

As shown in Figs. 5B and 11 studies (random model) were included in the analysis of sperm motility (SMD = −0.83 [-1.41, −0.24]; $P = 0.005$; $I^2 = 80\%$; Q test $P < 0.00001$). As shown in Table 2, the subgroup analyses showed that study heterogeneity (80%; Q test $P < 0.00001$) may be reduced in the restrained group (0%; Q test $P = 0.82$), in rats older than 10 weeks (28%; Q test $P = 0.22$), and in the mobile phone group (56%; Q test $P = 0.08$).

The sensitivity analysis showed that after removing the study by Ozlem et al. SMD was reduced to −1.00 (−1.49, −0.52) and I^2 was reduced to 66% (Q test $P = 0.002$; $P < 0.0001$), whereas the analysis results were not significantly changed after removing other studies. As shown in Figure S1B, the funnel plot, Begg's test (Pr = 0.06), and Egger's test (P = 0.111) did not suggest significant publication bias in the included studies.

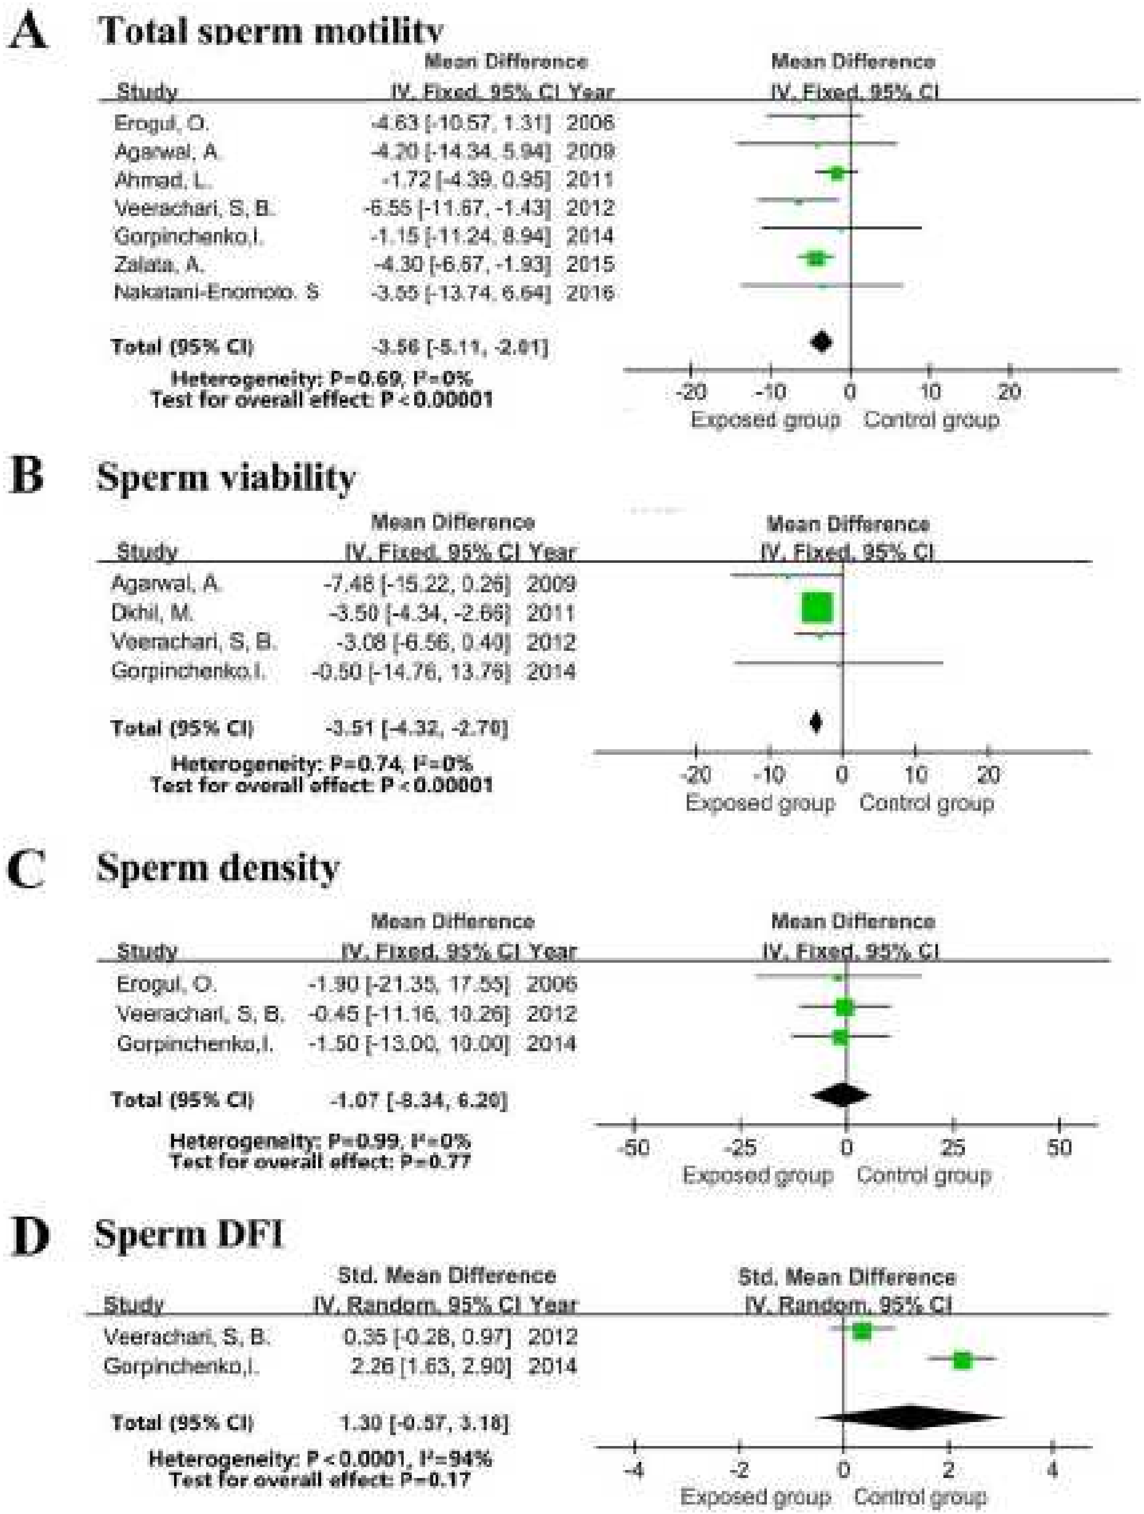

Fig. 4. Forest plot of sperm motility (A), viability (B), density (C), and DFI (D) in human studies *in vitro*. The pooled results supported the claim that mobile phone RF-EMR exposure reduces total sperm motility and viability of human sperm *in vitro*.

3.7.3. Sperm viability in rats

As shown in Fig. 5C, four studies (fixed model) were included in the analysis of epididymal sperm viability (MD = −8.20 [-10.33, 6.07]; $P < 0.00001$; $I^2 = 0\%$; *Q* test $P = 0.57$). The sensitivity analysis showed that excluding any study did not significantly change the observed total effect scale, I^2, *Q* test *P*, or the statistical *P*-value.

3.7.4. Sperm morphology in rats

As is shown in Fig. 5D, seven studies (random model) were included (SMD = −0.37 [-1.12, 0.37]; $P = 0.33$; $I^2 = 79\%$; *Q* test $P < 0.00001$). The subgroup analysis (Table 2) showed that I^2 decreased to 0% (*Q* test $P = 0.59$), and the *P*-value changed to 0.01 in the mobile phone group. Sensitivity analysis showed that after removing the studies by Nisbet et al. or Yahyazadeh and Altunkaynak, the SMD was reduced to −0.59 (−1.25, 0.08) and −0.13 (−0.70, 0.44), respectively, I^2 was reduced to 67% (Q test $P = 0.01$) and 68% (Q test $P = 0.008$), respectively, and P was 0.08 and 0.65, respectively. Removing other studies did not significantly change the pooled results. The funnel plots, Begg's test (Pr = 0.54), and Egger's test ($P = 0.48$) did not suggest significant publication bias in the included studies (Figure S1C).

3.7.5. Sperm density in mice

As shown in Fig. 5E, epididymal sperm density analysis included six studies (random model; SMD = −2.62 [-3.79, −1.44], $P < 0.00001$; $I^2 = 83\%$; Q test $P = 0.0001$). A subgroup analysis showed that there was no significant change in the analysis results after grouping by modeling device, exposure time, or age. The sensitivity analysis showed that removing any study did not significantly change the observed total effect scale, I^2, Q test P, and the statistical P-value, suggesting robustness of the results.

4. Discussion

In the past six years, studies on the effects of mobile phone radiation on sperm quality were mostly conducted using animal experiments rather than human surveys. Consistent with the results of a meta-analysis from 2014 (Liu et al., 2014), the pooled results of cross-sectional studies in our study did not suggest that mobile phone use is associated with a decline in human sperm quality. Current evidence from human sperm *in vitro* studies support the claim that mobile phone RF-EMR exposure can suppress sperm mobility and viability. The meta-analysis by Liu et al. suggested that mobile phone RF-EMR exposure can decrease sperm density and motility in rats (Liu et al., 2014). Our pooled results indicate that mobile phone RF-EMR exposure can reduce sperm motility in rats but that it does not significantly decrease sperm density ($P = 0.05$); moreover, our pooled results also suggest that mobile phone RF-EMR reduces sperm viability in rats, which has not been shown previously. Despite considerable heterogeneity among included human and animal studies, the large number of studies enabled us to conduct subgroup analyses to further analyze these heterogeneities caused by different experimental conditions.

4.1. Human cross-sectional studies

For the first time, our results suggest that differences in study areas may cause heterogeneity when investigating sperm quality, while the evaluation method contributed to heterogeneity of sperm motility results. Analysis of sperm density, motility, and morphology indicated that the respective studies in East Europe and West Asia were less heterogeneous. The fact that study area may be a source of heterogeneity may be due to differences in ethnicities, habits, and research methods; moreover, statistical fluke may not be ruled out, which should be considered in future studies.

There are three particularly important aspects of the present study. First, theoretically, if mobile phone use is associated with reduced sperm quality, such correlations should become stronger with increasing exposure time. Unfortunately, our present subgroup analysis failed to show that duration of phone use affected the pooled results or study heterogeneity, which may be attributed to the recall bias in the epidemiological survey on mobile phone use, which causes inaccuracy of survey results (Halgamuge et al., 2020). Second, the sensitivity analysis suggested that the study by Feijo et al. significantly affected the pooled results, which may be due to the authors' unique research method regarding mobile phone use as they recorded only speaking time (Feijo et al., 2011),

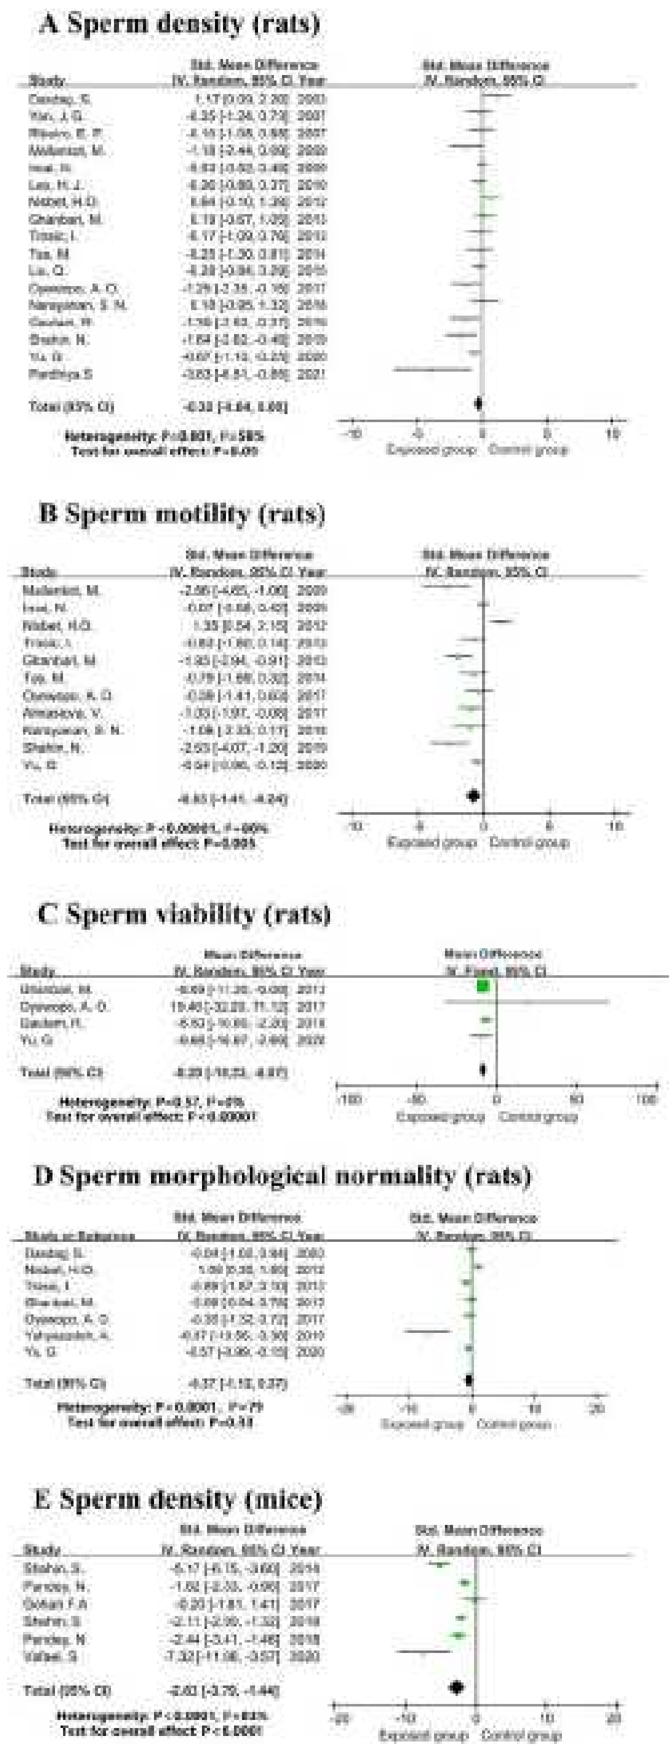

Fig. 5. Forest plot of sperm density (A), motility (B), viability (C), and morphology (D) in rat studies, and sperm density (E) in mouse studies. The pooled results suggested that mobile phone RF-EMR exposure reduced sperm motility and viability in rats, and sperm density in mice.

whereas other researchers recorded the entire duration of mobile phone use. The duration of mobile phone use is a broad concept that includes speaking time, thus in the future, researchers should take measures to accurately record mobile phone usage to obtain more reliable results. Third, in daily life, men who use their mobile phones for prolonged periods of time are frequently highly pressured and have irregular lifestyles; therefore, they are more prone to smoking, drinking, and other unhealthy habits which may affect sperm quality (Toda et al., 2006; Zhang et al., 2016). Compared with the effects of mobile phone use on reproductive functions, the effects of these confounding factors on sperm quality would be considerably stronger. Without distinguishing these factors, intragroup differences in sperm quality would increase, resulting in high heterogeneity in the analysis results. Therefore, further studies should consider the importance of using appropriate research and statistical methods that can eliminate the influence of confounding factors. In the MARHCS cohort study, Zhang et al. conducted multivariate analyses using health data of 794 men of childbearing age living in Chongqing, China, and after accounting for potential confounding factors such as smoking and drinking, extended speaking time on mobile phones was found to be a risk factor for the decline in sperm concentrations (Zhang et al., 2016). Apart from cross-sectional surveys, new ways of exploring the effects of mobile phone use on male health should also be encouraged. For example, Volkow et al. used positron emission tomography scanning technology to detect brain function changes in humans when talking on mobile phones, and they found that 50 min mobile phone exposure was associated with increased brain glucose metabolism in the region closest to the antenna (Volkow et al., 2011).

4.2. Human sperm in vitro studies

The pooled results of human sperm *in vitro* studies showed that mobile phone RF-EMR can affect mature sperm *in vitro*, leading to a decline in sperm motility and viability. These results suggest that when performing *in vitro* sperm manipulation in reproductive medicine, researchers should be attentive to the harmful effects of EMR including mobile phone RF-EMR. However, present evidence may not directly support that carrying mobile phones in trouser pockets adversely affects sperm quality in men, resulting in a decline in male fertility. The reason is that mature sperm are stored within the human body where they are shielded by several tissues such as the scrotal wall and the epididymal wall, and are protected by semen components. After passing through these tissue walls, the intensity of RF-EMR may have decreased sufficiently to not affect mature sperm.

The total number of studies included in the sperm DFI analysis was small, and heterogeneity of the results was large. For this reason, even though the pooled results suggested that mobile phone radiation did not affect sperm DFI *in vitro*, further studies are required to support this conclusion.

4.3. Animal studies

Over the past six years, the total number of animal studies on the effects of mobile phone RF-EMR on sperm function has significantly increased. Based on the pooled results, mobile phone RF-EMR suppresses sperm motility and viability in rats and decreases sperm density in mice. For the first time, our subgroup analysis suggested decreased heterogeneity of the pooled results of rats which were restrained during radiation exposure, which may be attributed to the fact that restrained rats received more consistent RF-EMR at larger doses than non-restrained rats. Further analyses showed that sperm density of restrained rats decreased significantly, which differed from the conclusions of Liu et al. as their results showed high heterogeneity (Liu et al., 2014).

Rats are sexually mature at 10–12 weeks of age, and environmental pollution can reduce sperm quality in immature or mature rats via different mechanisms (Berndston 1977). Age may also be an important factor affecting the heterogeneity of rat studies, which has been shown in our analysis of sperm density and motility in rats exposed to mobile phone RF-EMR. In addition, the results of the present study indicate that mobile phone RF-EMR causes a significant decrease in sperm density and motility in rats older than 10 weeks, whereas in rats younger than 10 weeks, exposure to mobile phone RF-EMR at an immature stage does not exert such significant effects. These results may be explained by the low energy of mobile phone RF-EMR and the strong recovery ability of immature rats.

Previously, Liu et al. hypothesized that exposure time and radiation devices may be important factors affecting between-study heterogeneity (Liu et al., 2014). The results of our study showed that exposure time contributed to heterogeneity when investigating sperm motility in rats; however, heterogeneity was large in the long-term exposure subgroup, which may be attributed to the considerable differences in exposure time between studies in this subgroup (the shortest and longest exposure durations were 168 h and 1095 h, respectively). Our results also supported the claim that radiation device type is another important factor that affected heterogeneity when investigating sperm density, motility, and morphology in rats. However, some inconsistencies were observed in the results of the respective subgroup analyses. Compared with the mobile phone group, the simulator group was less heterogeneous regarding sperm density and was more heterogeneous regarding motility and morphology. Generally, RF-EMR produced by simulators is theoretically more stable than that produced by mobile phones, thus heterogeneity in the simulator group should be lower. These inconsistencies may be explained by the results of our sensitivity analysis, which showed that the simulator group included the study by Ozlem et al. which significantly increased heterogeneity of the sperm motility analyses; in the morphology analysis, the simulator group included studies by Nisbet et al. and Yahyazadeh and Altunkaynak, which exerted substantial effects on the heterogeneity of pooled studies (Nisbet et al., 2012; Yahyazadeh and Altunkaynak, 2019). Unfortunately, our results cannot explain how these studies increased the heterogeneity of the pooled results.

Current animal studies have mostly investigated reproductive effects of systemic exposure. As male reproductive ability is affected by multiple tissues such as the hypothalamus, pituitary gland, and the testes (Ajayi et al., 2020), researchers only preliminarily explored whether mobile phone RF-EMR affects male fertility via experiments with systemic exposure. However, they could not determine the main reproductive organ through which mobile phone RF-EMR exerts these effects. The National Institute of Toxicology also proposed that investigating the effects of mobile phone RF-EMR on certain organs was important for further clarifying the mechanism of mobile phone RF-EMR exposure on human health when exploring the relationship between mobile phone RF-EMR exposure and cancer (NIEHS 2018). This perspective is also applicable regarding reproductive-toxicity research on mobile phone RF-EMR. Moreover, the development of 5G, smart multi-antenna, and beamforming technology may cause electromagnetic field energy to concentrate in local space, resulting in a locally high electromagnetic field pattern in certain organs. Research investigating local exposure to certain reproductive organs is thus becoming increasingly important and necessary. Lastly, it should be noted that some studies included in this meta-analysis were of low quality, and their research information was incomplete, which may have contributed to the high study heterogeneity and prevented in-depth analysis.

4.4. Personal views

In the present study, we did not perform a subgroup analysis of SAR owing to inconsistencies in the calculation of SAR values of reproductive organs in the reviewed studies. For many years, SAR has been recognized as a key index for evaluating environmental safety of mobile phone RF-EMR (Chen and Wang 1994). However, the current safety threshold of SAR can only reflect the thermal effect of RF-EMR and does not account for non-thermal effects (Gaestel 2010). In addition, the calculation of SAR is based on a fixed value of a human body model and does not consider the actual density, permeability, and dielectric constant of specific organs affecting SAR values (Sallomi 2012). Moreover, SAR measurements are not standardized. According to a previous report (Davis 2010), the SAR value of the same product varies substantially between measurements by different manufacturers. Thus, the current SAR threshold may not be sufficiently safe to protect human health. The academic community should identify other appropriate indices that are more suitable for health evaluation, and interdisciplinary cooperations should be established to redefine the safe threshold of mobile phone RF-EMR dosages.

Mobile phone RF-EMR is a low-energy electromagnetic radiation. The effects of this radiation on reproductive functions have been examined using some macro-indices such as sperm density, motility, and testicular morphology; however, normality of such indices does not necessarily preclude adverse effects of mobile phone RF-EMR on reproductive parameters. Further sperm-related functional and molecular indices (especially at the genetic and epigenetic levels) should be investigated because macroscopic occurrence of a disease is frequently the result of cumulative changes in the microenvironment.

Recently, low-dose toxins were suggested to alter the biological characteristics of cells (Fernandez-Antoran et al., 2019). Based on this, it is reasonable to assume that even though short-term or intermittent mobile phone RF-EMR exposure is not strong enough to damage organs, it may affect biological characteristics of germ cells, resulting in alterations of disease-resistance ability of the male reproductive system or, even more concerning, of offspring health. Therefore, further research is needed to explore this issue in depth.

Even though effects of mobile phone RF-EMR exposure on male fertility have been studied extensively, progress in this field is slow, and respective studies are limited regarding research scope and depth. Further studies revealing the reproductive effects of mobile phone RF-EMR are still of great practical importance because even if mobile phone RF-EMR exerts only minor effects on the human body and causes health problems in only a few permille of users, it may still result in a global medical catastrophe (Falcioni et al., 2018). With the development of model communication technology, the presence of mobile phone RF-EMR in our lives will increase (Eeftens et al., 2018; Havas 2017), and ignoring the problems caused by this radiation may lead to a lack of relevant protective measures and further decline in male fertility.

5. Conclusion

The results of our meta-analysis indicated that in East Europe and West Asia, mobile phone use is associated with a decline in human sperm density and motility. Mobile phone RF-EMR can reduce motility and viability of mature human sperm *in vitro*, and it can also reduce sperm motility and viability in male animals and decrease sperm density of sexually mature restrained rats. Some important factors that affect the results of animal experiments are study setup and radiation device as well as age and exposure time. Our study is an extension of previous studies and has scientific value for future studies on effects of mobile phone RF-EMR associated with sperm quality.

Abstract: Background: this study aims to estimate the rate of death by cancer as a result of Radio Base Station (RBS) radiofrequency exposure, especially for breast, cervix, lung, and esophagus cancers. Methods: we collected information on the number of deaths by cancer, gender, age group, gross domestic product per capita, death year, and the amount of exposure over a lifetime. We investigated all cancer types and some specific types (breast, cervix, lung, and esophagus cancers). Results: in capitals where RBS radiofrequency exposure was higher than 2000/antennas-year, the average mortality rate was 112/100,000 for all cancers. The adjusted analysis showed that, the higher the exposure to RBS radiofrequency, the higher cancer mortality was. The highest adjusted risk was observed for cervix cancer (rate ratio = 2.18). The spatial analysis showed that the highest RBS radiofrequency exposure was observed in a city in southern Brazil that also showed the highest mortality rate for all types of cancer and specifically for lung and breast cancer. Conclusion: the balance of our results indicates that exposure to radiofrequency electromagnetic fields from RBS increases the rate of death for all types of cancer.

Keywords: cancer; mortality; electromagnetic fields; breast neoplasms; lung neoplasms; esophageal neoplasms; uterine cervical neoplasms

1. Background

Mobile phones have become extremely common in modern times. Wireless technology has a large number of Radio Base Stations (RBSs), which transmit information through radiofrequency signals. In 2006, there were already more than 1.4 million RBSs in the world [1]. In the Brazilian capitals, RBSs were implemented in 1992 in Brasília (the capital of Brazil), and in 2017, there were 27,145 RBSs indexed in the capitals [2].

The effect of electromagnetic fields emanating from RBS on health is not very well known. The World Health Organization (WHO) reported, in 2006, that scientific knowledge indicates that RBS radiofrequency exposure is within the international standards and, therefore, does not pose a risk to human health [1]. However, in 2014, the WHO recognized the need to promote research to investigate the effect of the radiofrequency field on human health as a priority in order to fill the knowledge gaps [3]. Several issues relating to new wireless technologies are currently highlighted: the environmental impact of RBS radio frequency exposure, its effects on human health, its thermal effects, and its noise emission [4].

In Brazil, the National Telecommunications Agency (ANATEL) is the entity that regulates the electromagnetic emission of RBSs in accordance with the limits established by Resolution No. 700 of 28 September 2018 (Union Official Diary) [5]. In addition to ANATEL, telecommunication antenna installations are also regulated by municipal laws in order to minimize environmental and human health impacts [4].

Mobile phone-derived electromagnetic fields are classified by the International Agency for Research on Cancer (IARC) as possibly carcinogenic to humans [3,6,7]. The intensity of the RBS radiofrequency fields is higher near the antenna and decreases as the distance from it is greater [1,8]. In big cities, however, RBSs are located very close to populated areas, above or between homes and businesses. The antennas are so close to homes that the multi-story windows of residential buildings, for example, are side by side to these antennas [9].

Despite the scarce knowledge on this subject, there are few resources allocated to investigating the role of exposure to electromagnetic fields from RBSs on human health. In the United States, for example, until 2010, no funding had been reserved by government agencies to study the possible health effects on people living near RBSs [9]. This study aims to estimate the rate of death for cancer according to RBS radiofrequency exposure, especially by breast, cervix, lung, and esophagus cancers, which are among the most common cancers in Brazil for men, women, or both sexes.

2. Methods

This is an ecological study using capitals as the unit of analysis. We collected information on the number of deaths by cancer per gender, age group, Gross Domestic Product (GDP) per capita, death year, and the amount of exposure over a lifetime.

Information on deaths by cancer per gender and age was collected from the Mortality National System (SIM) from the Computer Science Department of the Unified Health System (DATASUS) website [10]. We investigated all cancer types and some specific types: (1) deaths by breast cancer (International Classification of Diseases 10th Revision (ICD10) group—malignant breast neoplasms), (2) deaths by cervix cancer (C54 category of ICD10—malignant neoplasm of the cervix), (3) deaths by lung cancer (C34 category of ICD10—malignant neoplasms of the bronchi and lungs), and (4) deaths by esophageal cancer (C15 category of ICD10—malignant neoplasm of the esophagus). The choice of these specific types of cancer for this study took into account the high frequency of new cases in women or in men. Current statistics from 2020 from the National Cancer Institute show that breast cancer had the highest number of new cases in 2020 for women (about 66,000 cases, corresponding to about 30% of cases). Cervical cancer was the third, with more new cases in 2020 in women. Lung cancer was the fourth with more new cases in 2020 in men and women, and esophageal cancer was the sixth with more new cases in men. With regard to mortality, data from 2018 indicate that the cancers selected for this study are among the top five in number of deaths. These values refer to both genders for lung cancer, to female strata for breast and cervical cancers, and to the male stratum for esophageal cancer [11]. Although brain cancer does not have a high frequency in Brazil and metastatic brain tumors are more frequent than primary brain tumors, as several studies have evaluated their relationship with exposure to electromagnetic fields, we have included the results of the analysis of this type of cancer in Supplementary Tables S1 and S2.

Census population data [12] and GDP were also collected from the DATASUS website [10]. The number of RBSs and the year they were implemented in each capital were collected from Telecommunication Service System [2].

People's exposure times were calculated according to birth and death years. The annual RBS radiofrequency exposure was calculated by summing the number of RBS implementations in each year multiplied by the people's exposure time. The total exposure was calculated from the sum of annual exposures.

A map with charts was built using the mortality rate per square kilometer (km^2) and the median of RBS radiofrequency exposure in the 2010–2017 period.

3. Statistical Analysis

We calculated the median and interquartile range of mortality rate per 100,000 according to the levels of explanatory variables. The Kruskal–Wallis test was used to access the statistical differences between groups.

Multilevel Poisson regression models were used to estimate the risk-adjusted mortality. The response variable was death by cancer, and the fixed effects were the logarithm transformation of RBS radiofrequency exposure, gender, age group, and death year. We also included an offset with the logarithm of population size. The random effects included capital city (intercept), square root transformation of GDP (slope), and capital's area per km^2 (slope). When the response variables were death by breast and cervix cancer, the gender was not included as a fixed effect, as only females were investigated.

The abovementioned logarithmic transformations and the square root transformation were used to normalize the distribution of variables. We used R-Project version 3.6.1 (R Foundation, Vienna, Austria) and ArcGis version 10.5 (Environmental Systems Research Institute, Redlands, CA, USA) to perform the analysis.

4. Results

For all cancers and for the specific types investigated (breast, cervix, lung, and esophagus cancers), the higher the exposure to RBS radiofrequency, the higher the median of mortality rate. In capitals where RBS radiofrequency exposure was higher than 2000/antennas-year, the median of the breast cancer mortality rate was 27.33/100,000, while for all cancers, it was 111.68/100,000 (Table 1).

RBS = exposure to radio base stations (antennas-year); IQR = interquartile range; sign = statistical significance − significance. * p-value < 0.001 and NS, p-value > 0.05.

Females showed the highest median of mortality rate for all cancers but specifically for lung and esophagus cancers; the highest median of mortality rate was observed in males (4.31/100,000 and 0.45/100,000, respectively) (Table 1).

For all cancers and for the specific types investigated, the higher the age group, the higher the median of mortality rate. Lung and breast cancers showed high medians of mortality rate (159.40/100,000 and 91.18/100,000, respectively) (Table 1).

The median of mortality rate for all types of cancer decreased from 68.76/100,000 to 61.87/100,000 over the period. For breast, cervix, lung, and esophagus cancers, it showed slight variations over the period, around 17/100,000, 7/100,000, 4/100,000, and lower than one per 100,000, respectively (Table 1).

In the adjusted analysis, the results showed that the higher the logarithm of RBS radiofrequency exposure, the higher the cancer mortality rate. The highest adjusted risk was observed for cervix cancer (Rate Ratio (RR) = 2.18) (Table 2).

Sqrt GDP = square root transformation of gross domestic product per capita; RR = rate ratio; Std Dev = standard deviation; Log RBS = logarithm transformation of radio base station radiofrequency exposure (RBS radiofrequency exposure = sum of the number of RBS in each year multiplied by the exposure time); sign = statistical significance − significance. *** p-value < 0.001; ** p-value < 0.01; * p-value < 0.05; and NS, p-value > 0.05.

A multilevel Poisson model was used to estimate the risk of cancer mortality. Except for breast and cervix cancers, which were estimated only for women, every adjusted models included as fixed effects the variables sex, logarithm of RBS, age group, and death year. The variables included as random effects were capital (intercept), GDP (slope), and area/Km^2 (slope). The offset of the population was also included in the models.

Males showed the highest adjusted risk of lung, esophagus, and all types of cancer (Table 2), although the median of mortality rate for all cancers was higher for females in the bivariate analysis (the results are shown in Table 1).

As expected, there was an increasing trend in the adjusted risk of cancer mortality in the older the age group. Compared to people younger than 30 years old, the adjusted risks were 297.55, 53.88, 1250.63, 2154.44, and 164.61 for breast, cervix, lung, esophagus cancer, and all cancers, respectively (Table 2).

For cervix cancer and all types of cancers, there was a decreasing trend in the adjusted risk of cancer mortality for more recent periods. For lung and esophagus cancers, this trend is observed from 2014–2015 period (Table 2).

The inclusion of random effects was significant in every models for the following effects: “capital” (intercept) and “square root of GDP” (slope). However, for the “area of the capital” (slope), it was significant only for esophagus cancer. For all models, the greatest standard deviation of random effects was observed for the “capital” (intercept) (Table 2).

The spatial descriptive analysis showed that the highest median of RBS radiofrequency exposure was observed in Florianópolis (South of Brazil) (44.23 antennas-year/km^2). Florianópolis also has the highest mortality rate per km^2 for all types of cancer and specifically for lung and breast cancer (0.09/100,000, 0.31/100,000, and 0.93/100,000, respectively). Recife (Northeast) and Belo Horizonte (Southeast) showed medians of RBS radiofrequency exposure higher than 20 antennas-year/km^2, and their mortality rates per km^2 for all cancers were 0.29/100,000 and 0.19/100,000, respectively. Vitoria (Southeast), Teresina, Fortaleza, Natal, and Aracaju (both in Northeast) showed medians of RBS radiofrequency exposure higher than 10 antennas-year/km^2, and mortality rate per km^2 for all types of cancer were 0.60/100,000, 0.49/100,000, 0.21/100,000, 0.35/100,000, and 0.38/100,000, respectively (Figure 1).

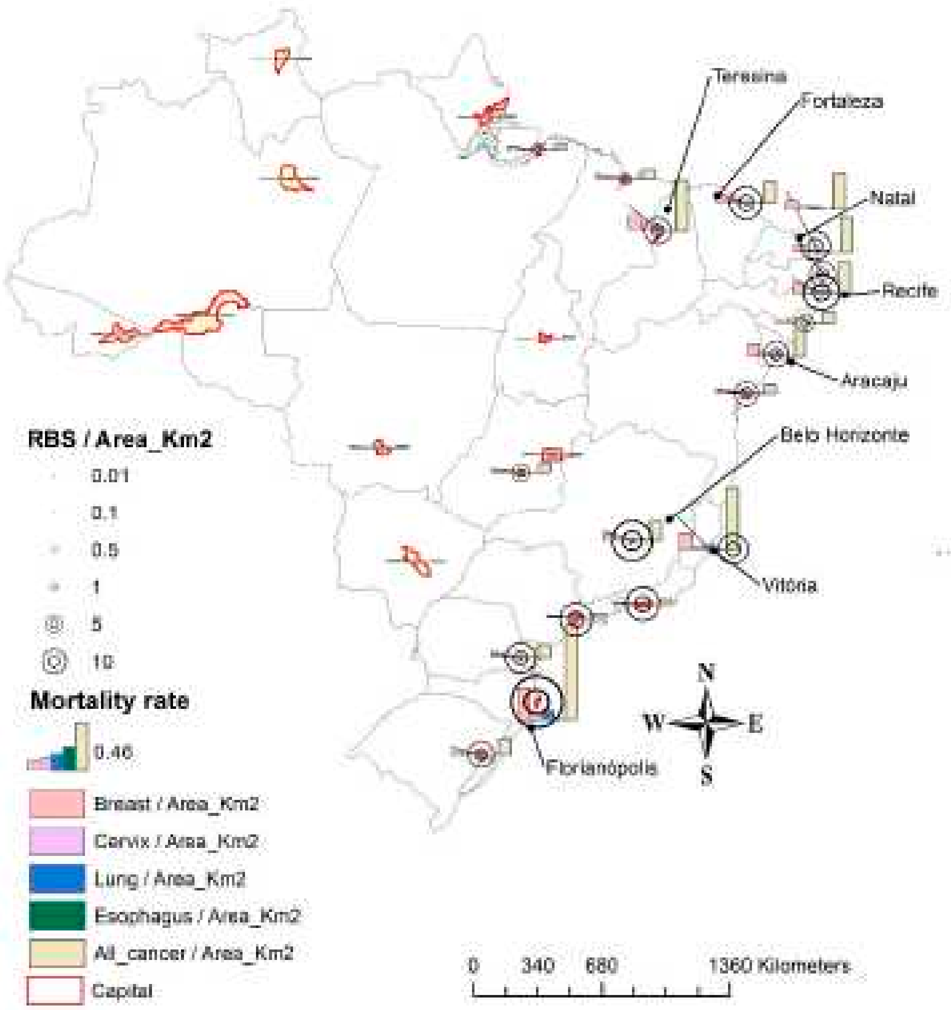

Figure 1. Distribution of the cancer mortality rate in each capital and their experience of exposure to radio base stations radiofrequency, 2010–2017. RBS = median of the number of radio base station radiofrequency exposure (RBS radiofrequency exposure = sum of the number of RBS in each year multiplied by the exposure time). RBS/Area_Km2 = median of the number of RBS per Km^2. We used the median of mortality rate. Breast/Area_K2, Cervix/Area_K2, Lung/Area_K2, or Esophagus/Area_K2 = median mortality rate for a specific cancer type per Km^2.

5. Discussion

The biological effects of exposure to electromagnetic fields were investigated in some

5. Discussion

The biological effects of exposure to electromagnetic fields were investigated in some studies, mainly experimental studies with mice. The authors point out the following effects: an increase in the calcium efflux in human neuroblastoma cells, impairing cellular functions [13]; changes in the immune system [14]; a decrease in reproductive function [15]; an increase in serum testosterone levels [16]; an increase in permeability of the blood–brain barrier, which protects the brain from toxic substances, bacteria, and viruses [17]; and damage to cell DNA [18–20].

The evidence of radiofrequency radiation carcinogenesis has increased since 2011. Some animal studies suggest that exposure to electromagnetic fields accelerate the development of sarcoma colonies in the lung, mammary tumors, skin tumors, hepatomas, and sarcomas [21,22]. This study detected an increase in the rate of death by cancer in capitals where there is a greater exposure to electromagnetic fields emanating from radio base stations. Studies made in Stockholm (Sweden) indicate that high levels of environmental radiofrequency radiation are quite present in residential and commercial areas [23–25]. In the United Kingdom, at the beginning of 2009, there were 51,300 RBSs and two thirds were installed in existing buildings or other structures [9].

Dode et al., 2011, pointed that electromagnetic fields from telecommunication systems is an important environmental problem nowadays [8]. The authors detected 6724 deaths by neoplasia occurring within an area of 500 m from the RBS and 320 deaths within an area between 500 and 1000 m. The mortality rate within an area of 500 m was 34.76 per 10,000 inhabitants, while within an area of 1.000 m, the rate was 32.78 [8].

Although in the present study, we investigate all cancers, we also investigated breast, cervix, lung, and esophagus cancers separately. In a mortality study performed in Brazil, breast and lung cancers were among the main cancers related to radiofrequency electromagnetic fields from RBS radiofrequency exposure [8].

Breast and cervix cancer have cure rates of around 95% when diagnosed early [26]. Mortality from breast cancer continues to increase in Brazilian capitals, while mortality from cervical cancer remains stable, unlike what occurs in developed countries, in which mortality for these cancers is decreasing. Lung cancer has less chances to be cured when detected in the early stages (56%) [26]. Esophageal cancer is difficult to detect early. In most cases, the signs and symptoms only appear in more advanced stages of the disease [26].

Despite the advance in knowledge about cancer, not all countries seem to benefit from this advance. This is the case of low- and middle-income countries, where a significant portion of the population does not have access to diagnosis and treatment, decreasing their chances of survival.

In the present study, we detected that the higher the exposure to radiofrequency electromagnetic fields from RBSs, the higher cancer mortality is. A study conducted in Israel also found that low-frequency electromagnetic fields contribute to breast cancer development [27–29]. Others studies also referred to the relationship between cancer and radiofrequency electromagnetic fields [30,31], including in animal studies [32].

In addition to exposures to radiofrequency electromagnetic fields, we have to consider other factors that contribute to the increase in cancer incidence and mortality. In Brazil, about 70% of the population depends on public health [33], and there are difficulties accessing cancer diagnosis and treatment in public health services. Opportunistic screening is still adopted, performed only when the patient in the risk group comes to the health service and there is difficulty starting cancer treatment within 60 days, as required by Brazilian law [34]. The consequences of these problems are the worsening of the disease and the high number of preventable deaths.

The main risk factor for lung cancer is tobacco consumption, which is higher for males [35]. Tobacco consumption has been decreasing gradually in Brazil from 1980 to 2013 [36], and this decline may have contributed in some way to reducing lung cancer mortality in men over time [37]. The main risk factors for esophageal cancer are the high intake of hot drinks [38], alcoholic beverages, and tobacco; low ingestion of fruit and vegetable; and exposure to occupational agents like benzene, silica, and asbestos [39]. Family history is one of the most important breast cancer risk factors [40]. However, there are many other risk factors, such as aging, genetic mutations, reproductive history, dense breasts, past history of breast disease, previous treatment with radiotherapy, sedentary lifestyle, overweight or obesity after menopause, alcohol intake, and use of hormones and some oral contraceptives [41]. Cervix cancer risk factors are associated with the risk of Human Papillomavirus (HPV) infection. A high number of pregnancies and no regular preventive colpocytology are pointed out as risk factors to cervix cancer [42].

In the present study, a capital located in the south showed the highest RBS radiofrequency exposure and the highest mortality by cancer (Florianópolis). In fact, other studies have also reported high rates of cancer in this capital [43–47].

Our results showed that, in general, men had a higher mortality rate of esophageal and lung cancer and that this rate increases with age. In fact, the scientific literature corroborates these results [48–52].

In order to keep the cellular sets running, the radiofrequency transmitters installed on the tops, roofs, and façades of buildings and residences emit electrical and magnetic fields 24 h a day. However, it is known by scientific knowledge that the nonthermal magnetic component can penetrate deeper into the body than the electrical one [53].

A person can stand at a fixed distance to an RBS and be exposed to 100% of the maximum permissible exposure or 5% of it depending on the antenna height and the bystander altitude. Therefore, people living in the upper floors of a building located in front of the antennas receive radiofrequency corresponding to 100% of the maximum permissible exposure [54]. Those data were confirmed in the Post-Graduation Project conducted at the Federal University of Minas Gerais (UFMG), Brazil, based on measures made in the capital of the state inside 400 residences located near the RBS from 2015 to 2019, measurements made by “MRE Engenharia—Medição de Radiações Eletromagnéticas” [55].

The measured values of the electrical and magnetic fields have shown more human exposure to electromagnetic radiation in an area within a 500 m radius from the transmitter antennas of cellular telephony [8]. To avoid hazards to human health, the safest solution would be to switch off the RBS in an area within a 500 m radius from residences, workplaces, hospital areas, kindergartens, and buildings.

As a limitation, it is important to note that this study used cancer data from national Brazilian sources, which can provide underestimated rates at different levels according to the region. For example, a study conducted in northern Brazil found a large proportion of deaths classified as unspecified uterine cancer. After the proportional redistribution of these deaths, there was an increase of 46% in the average cervical cancer mortality rates [56]. Another study conducted in a northeastern region of Brazil highlights that, within the older age group, the number of deaths before and after correction showed a significant variation, especially for breast cancer, where variation reached 54% [57].

Still as limitations of the study, we highlight two more points. As this is an ecological study and due to the unavailability of individual dwelling time data, the time that each individual lived close to an RBS could not be accessed. The possible migratory movements could also not be considered for calculation of the amount of exposure to RBS radio frequency throughout life in the resident population. This was calculated only according to birth, death year, and the year in which the RBS was implemented. However, people could have been born in another city and then migrated to the capital where the death was recorded. The other point is the proximity of stations to places of residence that interfere with the level of exposure of individuals. As it is an ecological study in which the unit of analysis is the capital, this study did not take into account the distances between stations and homes.

6. Conclusions

The balance of our results indicates that the exposure to radiofrequency electromagnetic fields from an RBS increases the rate of mortality by all cancers and specifically by breast, cervix, lung, and esophageal cancers. These conclusions are based on the fact that the findings of this study indicate that, the higher the RBS radiofrequency exposure, the higher the cancer mortality rate, especially for cervix cancer (adjust RR = 2.18). The spatial analysis showed that the highest RBS radiofrequency exposure was observed in a city located in the southern region of Brazil, which also showed the highest mortality rate for all types of cancer and specifically for lung and breast cancers.

Environmental pollution caused by nonionizing electromagnetic fields increases continuously. The location of RBSs is still a controversial field with regard to their regulation. There are numerous RBSs installed in residential areas, including on their roofs. Some epidemiological studies indicate an increased risk of cancer close to RBSs. It is important that further epidemiological investigations are conducted to elucidate the role of the environment in radiofrequency signals on carcinogenesis processes.

REVIEW

Threshold of radiofrequency electromagnetic field effect on human brain

Hiie Hinrikus, Jaanus Lass, and Maie Bachmann

Tallinn University of Technology, Tallinn, Estonia

ABSTRACT

Purpose: This review aims to estimate the threshold of radiofrequency electromagnetic field (RF EMF) effects on human brain based on analyses of published research results. To clarify the threshold of the RF EMF effects, two approaches have been applied: (1) the analyses of restrictions in sensitivity for different steps of the physical model of low-level RF EMF mechanism and (2) the analyses of experimental data to clarify the dependence of the RF EMF effect on exposure level based on the results of published original neurophysiological and behavioral human studies for 15 years 2007–2021.

Conclusions: The analyses of the physical model of nonthermal mechanisms of RF EMF effect leads to conclusion that no principal threshold of the effect can be determined. According to the review of experimental data, the rate of detected RF EMF effects is 76.7% in resting EEG studies, 41.7% in sleep EEG and 38.5% in behavioral studies. The changes in EEG probably appear earlier than alterations in behavior become evident. The lowest level of RF EMF at which the effect in EEG was detected is 2.45 V/m (SAR = 0.003 W/kg). There is a preliminary indication that the dependence of the effect on the level of exposure follows rather field strength than SAR alterations. However, no sufficient data are available for clarifying linearity-nonlinearity of the dependence of effect on the level of RF EMF. The finding that only part of people are sensitive to RF EMF exposure can be related to immunity to radiation or hypersensitivity. The changes in EEG caused by RF EMF appeared similar in the majority of analyzed studies and similar to these in depression. The possible causal relationship between RF EMF effect and depression among young people is highly important problem.

Low-level RF EMF; nonthermal model; threshold; linearity; depression

Introduction

The world population has been exposed to man-made coherent electromagnetic radiation, different from the natural radiation emitted by the Sun, over a very long period of time without remarkable effects on health. The people are adapted to the level of radio and TV broadcasting radiofrequency electromagnetic field (RF EMF) about 0.1 V/m. During recent decades, the applications of mobile telecommunication technology have drastically changed the situation. The sources of RF EMF have moved closer to people and the levels of exposure are much higher. The current guidelines recommend health protection limits up to 61 V/m (ICNIRP 2020). Hundreds of studies have detected biological RF EMF effects in humans, animals and cells at the levels of exposure much less than existing health protection limits. According to the Ericsson Mobility Report, the number of mobile subscriptions by technology is over eight billion in 2020 (Ericsson Mobility Report 2020). This number is higher than the world population. The wide applications of RF EMF rise concern about possible consequences on health.

The increased oxidative stress caused by RF EMF exposure has been reported in many animal and cellular studies (Schuermann and Mevissen 2021). The relevant consequences on health (genome stability, immune system, neurodegeneration, reproduction) are likely. The radiofrequency electromagnetic field was classified as possibly carcinogenic to humans (class 2B) by the International Agency for Research on Cancer (IARC 2013).

The RF EMF effects on brain bioelectrical activity, cognition and behavior, not obligatory related to genome instability, have been a topic of interest over the past decades. The neurophysiological effects on humans have been detected in many experimental studies but the results are controversial (Valentini et al. 2007; Marino and Carruba 2009; Kwon and Hämäläinen 2011). The large variations in applied methods, different frequencies, levels of exposure and modulation parameters cause high diversity of the effects and results. The recent cohort study does not provide sufficient confirmation about the correlation between more extensive use of mobile phones and the reported symptoms nor sleep quality (Auvinen et al. 2019; Tettamanti et al. 2020). It is complicated to determine causal relationship between RF EMF biological effects and its health consequences due to diversity of exposure conditions and numerous concomitant other factors.

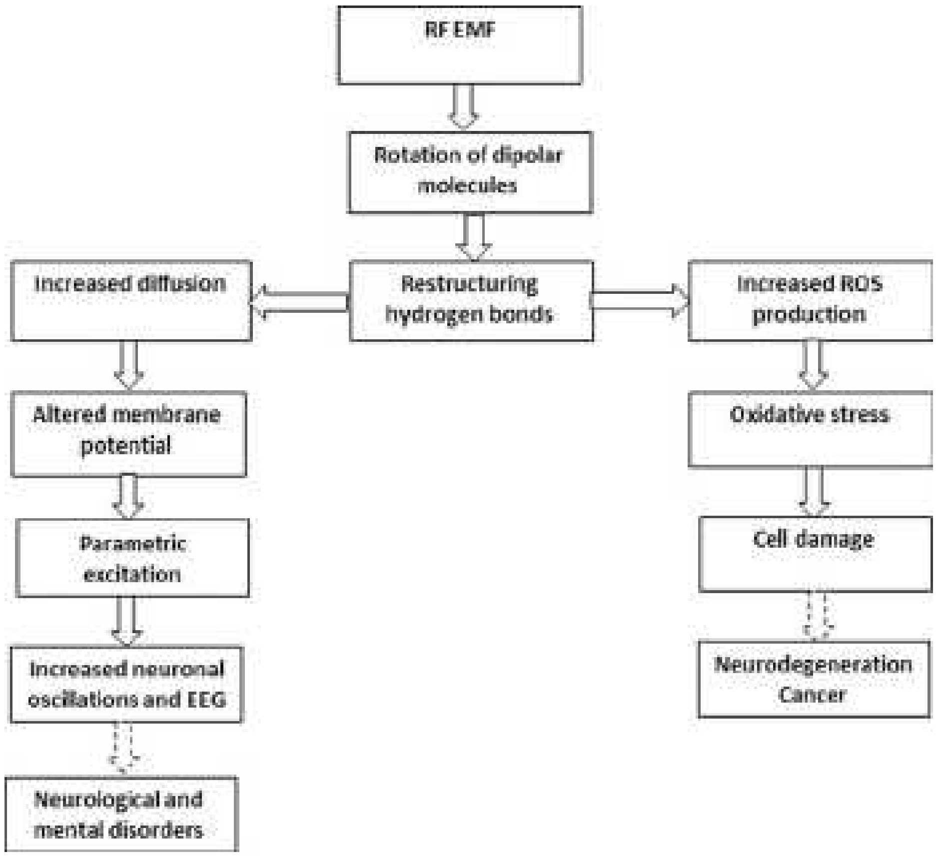

Figure 1. Model of nonthermal mechanisms of low-level RF EMF: left track neurophysiological effect, right track neurodegeneration.

Does the RF EMF has a threshold, lower of which the RF EMF does not have biological effect? This is an important question and crucial to avoid possible consequences on health.

Theoretical estimations for the sensitivity of living cells to electric field provided the threshold values about $10^{-6} - 10^{-7}$ V/m Hz$^{1/2}$ (Weaver and Astumian 1990; Hinrikus et al. 1998). In the case of wide-band telecommunication technology, the threshold rises: at 1 MHz bandwidth, the sensitivity is $10^{-3} - 10^{-4}$ V/m. However, these estimations used a simple single-cell model. Realistic model involving combinations of different cells, molecules and partly nonlinear physiological processes is highly complex. To the best of our knowledge, the calculations using complex model have been not performed.

To clarify the threshold of RF EMF effects, two approaches are applied in the current review: (1) the analyses of restrictions in sensitivity for different steps of the physical model of low-level RF EMF mechanism and (2) the analyses of experimental data to clarify the dependence of the effect on exposure level.

Analyses of different steps of the physical model of low-level RF EMF mechanism

The RF EMF is a physical stressor. Electric forces keep together atoms and molecules. The coherent RF EMF, due to regular synchronous electrical forces, causes stronger cumulative impact in a medium compared to random thermal processes (Hinrikus et al. 2018). Therefore, a nonthermal physical model based on electrical phenomena (Hinrikus et al. 2018) has been selected as a base for estimations. Figure 1 presents the logical structure of the mechanisms of the model. The low-level RF EMF approach, without heating, is appropriate in considering threshold of the effect.

Origin of the effect

The RF EMF causes displacement of free and bound charges in a dielectric medium and dielectric polarization of the medium. Displacement of electrons or ions inside a molecule leads to electronic or molecular, rotation of dipolar molecules to orientational polarization (King and Smith 1981). The intermolecular and even intramolecular electrical fields are much stronger than the applied RF EMF. Therefore, the imbalances in the spatial distribution of charges created by a RF EMF are very small. The synchronization of the displacements in a very large number of molecules leads to the measureable dielectric permittivity of materials (Zahn 2003).

Whereas the intramolecular electric forces are weaker than intermolecular forces, the orientational polarization dominates. Traditionally, the rotation of dipolar molecules caused by high-level RF EMF is considered as the origin of RF EMF thermal effect. However, the measureable electric permittivity exists also in low-level RF EMF and, consequently, the rotation of dipolar molecules takes place in low-level RF EMF at constant temperature. The synchronous cumulative impact of coherent RF electric field makes possible the low-level field-induced effect despite the energy of RF EMF is lower thermal energy causing random displacements (Hinrikus et al. 2018).

The polarization in dielectrics and water as well as dielectric parameters of tissues have been investigated in many studies (Hasted 1973; Pethig 1979; Mudgett 1985; Foster and Schwan 1995; Gabriel, Gabriel, et al. 1996; Gabriel, Lau, et al. 1996). The relaxation time of orientational polarization decreases with temperature due to increasing number of collisions disturbing the rotation. Therefore, the orientational polarization of tissues decreases with temperature (Pethig 1979).

Orientational polarization depends on the frequency and decreases with frequency due to inertia of molecules. Experimental data indicate that the dielectric constant has the frequency independent value of 1.8 at frequencies close to 100 GHz where the dielectric constant is determined only by the molecular polarization (Hasted 1973).

No theoretical nor experimental data about the threshold of polarization are available. In a linear medium, dielectric constant most probably is constant and does not depend on the level of EMF. The linearity of the response of living tissues to electromagnetic forces can be presumed at low level of EMF. Therefore, the rotation of dipolar molecules has no a determined threshold.

The synchronous rotation of dipolar molecules presumes unavoidable restructuring and weakening of hydrogen bonds between these molecules (Hinrikus et al. 2018). Hydrogen bonds are responsible for the properties of water and for holding together the DNA double helix. Hydrogen bonds are being constantly broken and reformed in liquid water because of random thermal motion of molecules despite the bonding energy is higher kT (Petrucci et al. 2007). The induced by low-level microwave radiation alterations in the properties of water demonstrate restructuring of hydrogen bonds by RF EMF (Fesenko and Gluvstein 1995). Consequently, kT does not determine the threshold of the phenomenon. There are no data about the threshold of restructuring the intramolecular bonds.

Neurophysiological effect

The left tract in Figure 1 presents the model of neurophysiological RF EMF effect that presumes no oxidative stress nor cellular damage.

Hydrogen bonds are responsible for many of the properties of water including viscosity. Weakening of hydrogen bonds decreases viscosity and increases diffusion. The caused by RF EMF increase in diffusion at constant temperature has been demonstrated by experiments in water and supported by the results of in vitro study (Hinrikus et al. 2015; Aly et al. 2008). Diffusion plays crucial role in many physiological processes including neuronal membrane potential and transfer of neurotransmitters in synapses. There are no factors nor data determining the threshold of the effect on diffusion.

Alterations in diffusion cause change in resting neuronal potential and misbalance of membrane currents (Malmivuo and Plonsey 1995; Hinrikus et al. 2017). No factors causing the threshold of membrane potential change have been reported (Malmivuo and Plonsey 1995).

The modulation of RF EMF at low frequencies close to the brain physiological frequencies is important and determines the intensity of the effect (Sanders et al. 1985; Hinrikus, Bachmann, Lass, Tomson, et al. 2008; Hinrikus, Bachmann, Lass, Karai, et al. 2008; Juutilainen et al. 2011). Low-level pulse-modulated RF EMF causes periodic alterations in neuronal electric parameters.

Periodic alterations of neuronal parameters can lead to parametric excitation of neuronal oscillations at predetermined electroencephalographic (EEG) frequencies (Hinrikus, Bachmann, Karai, et al. 2011). The process of excitation of parametric oscillation in a system has a threshold determined by the damping factor and losses in the system (Tso and Caughey 1965; Butikov 2004). However, biochemical energy compensates the losses in neuronal oscillations in brain. Therefore, the lower limit of parametric excitation is not defined. Disturbances in brain bioelectrical activity probably lead to alterations in cognition and behavior.

The brain's defense mechanisms can easily compensate the mild alterations caused by RF EMF (Bachmann, Tomson, et al. 2007). The fast compensation has been demonstrated in the experiments with RF EMF one minute ON-OFF pulse modulation: the effect has appeared statistically significant during first 30 s of ON-pulse but not significant during second 30 s (Hinrikus, Bachmann, Lass, Tomson, et al. 2008). However, in the case of continuous long-term exposure in RF EMF environment, the effect becomes permanent and consequences on health are possible.

Neurodegeneration

The right tract in Figure 1 presents the possible biological model of RF EMF effect that presumes oxidative stress and cellular damage.

The experimental results have demonstrated low-level RF EMF induced increase in the level of reactive oxygen species (ROS) (Xing et al. 2016; Marjanovic Cermak et al. 2018). The RF magnetic fields have been shown to affect the concentrations of ROS via the radical pair mechanism (Usselman et al. 2014; Castello et al. 2014; Barnes and Greenebaum 2015). The low-level RF EMF caused oxidative stress has been reported in many animal and cellular studies (Schuermann and Mevissen 2021). Oxidative stress can lead to cell damage. Further consequences in health including genome instability, neurodegeneration, immune system, male and female reproduction system are possible (Schuermann and Mevissen 2021).

Whereas body's defense mechanisms can repair the temporal changes in ROS formation process in brain cells, the health effect does not necessarily become evident. However, the probability that the defense mechanism can repair the changes caused by permanent exposure by RF EMF is much smaller.

The analyses of both models indicated no data about the factors determining the threshold of low-level RF EMF effect. The radiological protection system in low-level ionizing radiation still bases also on 'linear, no threshold' model, which assumes that there is no dose so small that it has no effect (McLean 2017).

Analyses of experimental data

Search of studies

The current review analyses the results of published original RF EMF human studies for 15 years 2007–2021. The EMF portal database was used for searching of publications. The filters: radio frequency, mobile communication, experimental studies and keywords: EEG, cognition, behavior were used for selection. Further individual evaluation excluded animal and in vitro studies. The quality of all studies was evaluated and the studies with drawbacks in used methods (insufficient data about exposure, limited numbers of subjects, incorrect statistics) were excluded. Finally, 76 relevant studies were included for the analyses.

RF EMF effects

Table 1 summarizes the RF EMF effects reported in the selected publications. The results are presented according to the formulations used by the authors. Unfortunately, the majority of studies do not report quantitative information about the effect – the numerical values of the analyzed parameters (e.g. values of changes in the powers of EEG rhythms or other parameters).

The effects are divided into four categories: changes in resting electroencephalography (EEG), in sleep EEG and sleep quality, in event-related potentials (ERP) plus cognition-behavior and others (changes in cortex oxygenation and brain glucose metabolism). Figure 2 presents the distribution of studies according to these categories. The resting EEG constitutes the largest part 47% of the total studies. The resting eyes closed EEG is most thoroughly investigated. The part of studies in sleep EEG and sleep quality constitutes 15%. The part of event-related potentials (ERP) connected to cognition and behavior effects constitutes 34% of total findings and the part of others only 4%.

Figure 3 presents the rate of studies, which revealed RF EMF effect in different categories. The relative part of

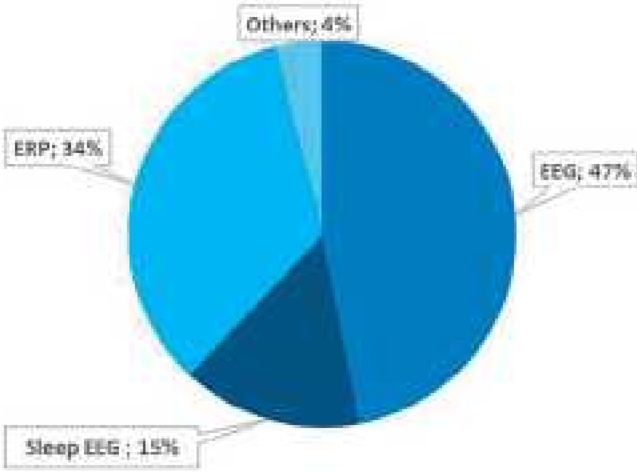

Figure 2. Relative distribution of studies according different categories of the RF EMF effects.

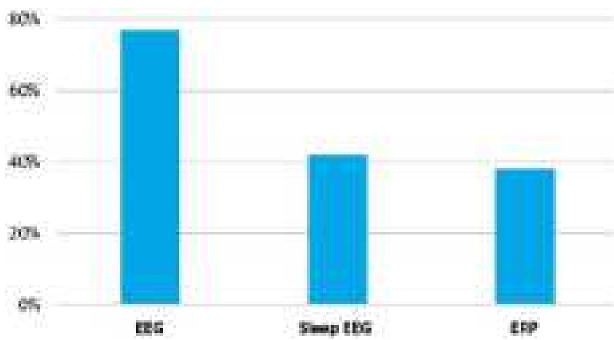

Figure 3. The rate of studies revealing RF EMF effects according different categories.

studies reporting the effect in the resting EEG category is about twofold higher than in the other sleep EEG or ERP categories. All three studies in the category others reported RF EMF effects. However, three studies are too few to make a conclusion about the rate of RF EMF effects.

Resting EEG

The rate of positive findings in resting EEG category (in total 30 studies) is 76.7%. The increased alpha power was most frequently reported (14 studies). Somewhat less studies reported increased beta power (6 studies). Decrease in alpha power was revealed only in two studies and beta power in one study. Increase in gamma power was detected in three and theta power in one study. Increased complexity was evident in three studies. Such distribution of the reported effects is obviously caused by the properties of the resting eyes closed EEG where alpha power (band 8–12 Hz) peak is much higher other bands. Therefore, the alterations in alpha power are detectable more easily.

Only few studies have applied advanced EEG analyses to detect alterations in more complicated nonlinear processes in the brain (Hinrikus, Bachmann, Karai, et al. 2011; Bachmann, Tomson, et al. 2007). The results of these studies demonstrated that RF EMF affected complexity of the brain bioelectrical activity. The RF EMF increased scores of both applied measures, Higuchi's fractal dimension (HFD) and Length distribution of low variability periods (LDLVP).

The results demonstrate that RF EMF causes excitation of brain and related increase in resting EEG alpha and beta bands powers. Exposure to radiation leads also to the higher complexity of brain bioelectrical activity.

Sleep EEG and sleep quality

The rate of positive findings in sleep EEG and sleep quality group is 41.7%. All five studies that reported the effect, declared increase in sleep EEG rhythms or spindles. The increase was evident in slow wave (delta and theta) and in alpha band. No disturbances in sleep quality were reported.

These results suggest that the radiation causes changes in neuronal activity earlier than the subjective feelings become evident.

Event-related potentials (ERP), behavior and cognition

The rate of positive findings in ERP, behavior and cognition group is 38.5%. The reported findings are diverse. Two studies reported changes in ERP. Improved behavior (memory, attention, reaction time) was demonstrated in four studies and reduced behavior (psychological arousal, correct answers, pain threshold) were shown also in four studies.

Exposure to low-level RF EMF, stimulating brain, can cause some improvement of behavior. On the other side, negative impact on behavior and arousal is evident.

Others

Positron emission tomography (PET) study reported significantly correlated with the estimated RF EMF amplitudes changes in brain glucose metabolism and its increase in the region closest to the antenna (Volkow et al. 2011). Another PET study indicated reduced cerebral metabolic rate of glucose in in the area close to the antenna (Kwon et al. 2011). The exposure did not affect task performance (reaction time, error rate). One study, using functional near-infrared spectroscopy, reported a slight influence of the RF EMF on frontal cortex oxygenation (Curcio et al. 2009).

These results support the suggestion that short-term changes in brain physiology are not obligatory related to human performance.

Dependence on exposure level

To study the dependence on exposure level, the selected for analyses studies are divided into groups according to exposure level (Table 2). While studies at SAR > 2 W/kg are considered as a single group, the numbers of studies per group are following: 7 studies in the group of SAR > 2; 22 studies in the group of SAR = 2–1.5 W/kg; 19 studies in the group of SAR = 1.5–1 W/kg; 10 studies in the group of SAR = 1–0.5 W/kg; 15 studies in the group of SAR =0.5–0.1 W/kg; and three studies in the group of SAR < 0.1 W/kg.

Table 2. Studies grouped according to the level of exposure.

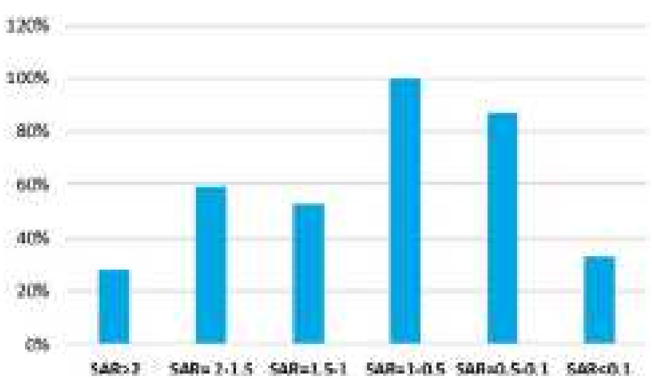

Figure 4. The rate of detected RF EMF effects in the groups of different SAR (W/kg) levels.

Figure 4 presents the rate of detected RF EMF effects in the groups. No any regular trend on the dependence of the effect on SAR level occurs. Unfortunately, only very few studies reported quantitative data about the intensity of the detected effects. The differences in the results can be caused rather by diversity of applied methods and used types of radiation. The fact that all studies at SAR = 1-0.5 W/kg indicated the effect can be considered as a chance. The group includes studies from different groups and various kind of the effects, no any reason exists for systematic advantage. The high rate of the detection 87% in the group SAR =0.5-0.1 W/kg can be explained by fact, that the majority of studies belong to one team. The team (Bachmann, Hinrikus, et al. 2007) has modified the modulation method used in Dicke radiometer (Tiuri 1964) to increase the sensitivity for the detection of changes in EEG. Therefore, small hidden in the variability of EEG changes can be detected and alteration not only in alpha but also in beta and gamma bands become evident.

The other reason for uncertainty of the results of analyses is that the majority of studies have been performed within quite narrow diapason of SAR levels between 2 and 0.1. Only few studies used higher and lower exposure levels.

According to the origin of low-level RF EMF effect mechanism (Figure 1), the effect is related to electric field strength causing rotation of dipolar molecules, not absorbed power. Therefore, electric field strength is more appropriate parameter for determining the experimental condition. Unfortunately, only very few authors have indicated field strength used in their experiments.

The dependence of the effect on exposure level can be evaluated better comparing data at two or more levels of exposure within the same study. Several studies performed experiments at two different SAR values. However, some of these studies reported no effect (Kleinlogel et al. 2008a, 2008b; Sauter et al. 2011; Danker-Hopfe et al. 2011; Eggert et al. 2015). Some others did not provide quantitative data for the results (Leung et al. 2011; Loughran et al. 2013; Sauter et al. 2015; Verrender et al. 2016; Dalecki et al. 2018).

Only one study reported quantitative data about changes at two different levels of exposure (Suhhova et al. 2013). At the higher SAR = 0.303 W/kg ($E = 24.5$ V/m) level, increases in the EEG beta2 (157%), beta1 (61%) and alpha (68%) frequency bands were detected. At the lower SAR = 0.003 W/kg ($E = 2.45$ V/m) level, increase only in the beta2 (39%) frequency band was evident. The decrease in the intensity of the effect at lower level about four times is much less than expected according to the decrease of SAR (100 times). The relative decrease of the effect is rather close to the change in field strength (10 times).

The performed analyses are not helpful in clarifying regularity of the dependence of the effect on the level of radiofrequency radiation. Obviously factors other than the level of exposure plays important role in the low-level RF EMF effects. An important factor is modulation frequency that is expected being close to the EEG frequencies (Hinrikus, Bachmann, Lass, Tomson, et al. 2008; Hinrikus et al. 2011). According to studies analyzed in the current review, the lowest electric field strength at which the effect was detected is 2.45 V/m (SAR = 0.003 W/kg) (Suhhova et al. 2013).

Possible consequences on health

The transformation of the biological effects of radiation into health consequences is a chaotic process (disrupted-line arrows in Figure 1). A very weak initial alteration on neuronal or molecular level can lead to unpredictable consequences on health – or not cause any remarkable health effect. Therefore, the threshold of RF EMF consequences on health cannot be determined.

Main attention in evaluation of the RF EMF health effects has been directed to risk of tumors (Carlberg et al. 2013; Miller et al. 2019; Choi et al. 2020). Due to long latent period, diverse exposure conditions and biological parameters, the causal relationship is difficult to reveal. The recent meta-analyses of case-control studies found that cellular phone use with cumulative call time more than 1000 h statistically significantly increased the risk of tumors (Choi et al. 2020).

Less attention in evaluation of the RF EMF health effects has been directed to neurological diseases and mental disorders. There is a possibility that the RF EMF neurophysiological effect can cause neurological and mental disorders not obligatory related to oxidative stress and genetic instability. The cohort study on cellular telephones and central nervous system diseases risks observed the excesses of migraine and vertigo and a possible association with dementia and Parkinson (Schuz et al. 2009). The recent cohort study concludes that people using mobile phones most extensively reported weekly headaches slightly more frequently than other users (Auvinen et al. 2019).

The analyses in the current review show that alteration in EEG are similar in the high majority of the studies: increase in EEG alpha, beta and gamma band levels as well as higher complexity of the signal (Table 1). Similar changes in EEG are characteristic in major depression disorder (Knott et al. 2001; Fingelkurts and Fingelkurts 2015). Based on these EEG parameters, the quantitative measures for the detection of symptoms of depression have been discussed (Ahmadlou et al. 2012; Hosseinifard et al. 2013).

The causality between the RF EMF and depression is not clear. The results of the study based on a special questionnaire indicated association between higher mobile phone use and symptoms of depression (Thomee et al. 2011). However, it is complicated to differentiate between the direct effect of RF EMF and psychological factors related to the high use of mobile phones leading sometimes even to addiction (Gutiérrez et al. 2016; Lapierre et al. 2019).

Depression has become a common mental disorder during last decades with the highest prevalence among individuals aged 18-25 (13.1%) (NIH 2021). The levels of RF EMF have increased and the use of mobile telecommunication technology has become more intense with prevalence in young people during the same period. Is this a coincidence or causality?

The results of some studies demonstrate that at the same level of RF EMF exposure and identical conditions, only a part of people are affected (Hinrikus, Bachmann, Lass, Karai, et al. 2008; Bachmann, Tomson, et al. 2007). The rate of sensitive people varies from 13% to 31% depending on modulation frequency (Hinrikus, Bachmann, Lass, Tomson, et al. 2008). It is not clear are some people ‘immune’ to the RF EMF permanently or occasionally. The connection between ‘immunity’ and hypersensitivity is important for interpretation of RF EMF health effects.

The results of some studies indicate that RF EMF-related changes in neuronal system (EEG signal) are much more frequent than in subjective behavior (Vecsei et al. 2018). The exposure-induced effects have been seen in objective indicators (EEG, glucose metabolism) but not in cognitive performance (Schmid, Murbach, et al. 2012; Kwon et al. 2011). Therefore, people would not mention existing health symptoms of the RF EMF effect. The situation that objective physiological symptoms appear earlier than the subjective feeling and symptoms is quite usual in the case of many diseases.

Conclusions

The analyses of the model of the non-thermal mechanism of RF EMF effect shows that the steps of the model contain no principal threshold for the effect. Therefore, the only way to estimate the possible threshold is analyses of experimental data. The review of experimental data of human RF EMF neurophysiological effects results in following main conclusions that indicated the directions of future research:

1. The lowest field strength that has caused the effect in EEG, according to the reviewed studies, is 2.45 V/m (SAR = 0.003 W/kg), close to the radio and TV broadcasting RF EMF field strength about 0.1 V/m. The future large-scale human, animal and in vitro studies are required to clarify the level and to increase the reliability of the experimentally determined threshold of RF EMF effect.
2. There is a preliminary indication that the intensity of the effect follows rather the field strength than SAR alteration. However, no sufficient data are available for clarifying regularity and linearity-nonlinearity of the relationship. The studies with systematic variations in exposure level (electric and magnetic field strengths, power density) would help to advance the field. The

research from cellular to humans is needed in this direction.
3. Very limited data are available about the repair and adaptive phenomena important in the interpretation of the RF EMF effects on health. Special studies are required to clarify the mechanisms and possibilities of the repair processes.
4. The finding that only part of people are sensitive to RF EMF exposure can be related to immunity to radiation or hypersensitivity. The variability of sensitivity between people and long-term stability of the status required large-scale long-term experimental studies.
5. The indication that the changes in EEG caused by RF EMF appeared similar to these in depression need a special attention. The fast increase of depression with the highest prevalence among young individuals and more intense use of mobile telecommunication technology with prevalence in young people during the same period needs attention. The possible causal relationship between RF EMF effect and depression among young people is the problem of high importance. The methodology and large-scale investigations in this direction are required.
